# PREFACE

A decade has passed since we wrote the previous edition of Crofton and Douglas, in conjunction with our late colleague Gordon Leitch. Gordon's untimely death, giving his life while saving those of others, was a very sad blow not only to his family but also to his many friends and colleagues in Scotland and over the world. His work in the control and management of tuberculosis continued in the footsteps of Sir Robert Philip and Sir John Crofton, and he would undoubtedly have made a most important contribution to the international battle against the disease had he survived. He was also a splendid all-round physician; something of the flavour of this comes across in the chapters he contributed to this book and which he delivered to us just the day before he left on his tragic holiday.

The first edition of this book was published in 1969, at the end of an era in which medical research had made the most notable contributions to the direct care of patients and to the prevention of disease, marked by the discovery of antibiotics and antituberculous chemotherapy, the demonstration of the harmful effects of smoking, and the elucidation of the structure of DNA. The original volume was a relatively slim one, written by our distinguished predecessors, John Crofton and Andrew Douglas, who had themselves played a major role in the battle against tuberculosis. At that time, respiratory medicine was looking towards an uncertain future, as tuberculosis declined and other respiratory diseases remained firmly in the realm of the generalist. *Crofton and Douglas's Respiratory Diseases* was perhaps the major factor in helping chest physicians of that era find their new role, allowing us to assert the importance of respiratory disease as a cause of morbidity and mortality in both the developed and poor worlds.

The intervening three decades have seen great changes in the practice and basic science of respiratory medicine, which is now recognized as a main-line acute specialty responsible for the care of a high proportion of the sick in all countries. That our patients are often from the least privileged sections of society has meant that funds for research and clinical care have not always been so easy to obtain as in more glamorous disciplines, but we can look back with some satisfaction to the control of tuberculosis

in Britain and the improved outlook for young victims of cystic fibrosis. We have, however, made little impact on the prognosis of lung cancer, have not had as much success as we would have liked in the battle against the amoral tobacco industry, and have watched in dismay as poor medical practice in other countries has encouraged the development of multi-drug resistant tuberculosis. And, in spite of all the research in the subject, we have seen asthma become progressively more prevalent in children. In our day-to-day care of sick patients, we must not take our eyes off the public health aspects of our specialty.

The previous edition of this book was well-received, and its translation into Greek and Italian, together with its production in a low-cost Asian edition, served as a reminder to us of the need to write for a world-wide readership. In this edition, we have reflected the increase in understanding of disease processes that has accrued from basic research, but we have also endeavoured to maintain the tradition of writing for the practising physician, who sees a multitude of patients with diseases common and rare, and who needs guidance on diagnosis and management. We are grateful to a number of friends and colleagues for agreeing to contribute to this edition and believe that their chapters, emphasizing the common and important, will contribute greatly to the value of the book.

One of the benefits of writing a book such as this is the amount one learns or re-learns by reading the references necessary to check up on one's statements. We have maintained a substantial bibliography, and this includes a number of older references that give graphic original accounts of diseases. It is not uncommon for old lessons to be forgotten and omitted from modern databases; while no textbook can hope to be as up-to-date as these databases, we hope we will help readers to avoid missing important earlier work while still keeping abreast of recent advances. We see this as a book to be used on the ward and in the office, where clinical problems arise and questions are asked and need clear answers.

Anthony Seaton  
Douglas Seaton

---

# ACKNOWLEDGEMENTS

The observant reader will have noticed the similar names of the two editors. We should like to acknowledge certain aspects of our genetic and environmental heritage. Our late father, Dr Ronald Seaton FRCP, was a pioneer in anti-malarial chemotherapy. He inspired us to become doctors and passed on to us a broad, lively and sometimes slightly cynical interest in medicine. From our mother, Julia, a nurse who worked with Lord Moynihan in Leeds and is still busy looking after others as she approaches her tenth decade, we have inherited an aversion to a moment's idleness. We have been fortunate in our teachers, notably the late Harold Edwards who introduced us to biology and evolutionary theory at school, Dr Colin Ogilvie of Liverpool who first interested us in respiratory medicine, and Professor Keith Morgan who introduced us to the scientific basis of clinical and preventive medicine in the wilds of West Virginia, USA. Many other teachers and colleagues have of course influenced us and continue to do

so, not least our juniors who impose a constant challenge to keep up-to-date.

With respect to the production of this book, we acknowledge with gratitude the tolerance of Blackwell's over our problems with deadlines and, especially, the courtesy and efficiency of Anna Woodford and the production staff. Our thanks also to the copy editor Jo Phillips for his attention to detail and his patience. We should also like to acknowledge the help of Dr Keith Kerr in providing pathological photomicrographs, Dr Lesley Gomersall for help in providing radiographs, and the Medical Illustration Department of Aberdeen University Medical School.

Most importantly, we record our gratitude to our wives, Jill and Anja, for putting up with our prolonged absence at our computers and for nevertheless helping and supporting us throughout this protracted endeavour. We promise to spend more time with them in future.

# DEVELOPMENT AND STRUCTURE

ANTHONY SEATON

The respiratory system brings air into close relationship with the mixed venous blood, allowing tissue respiration by uptake of oxygen into the circulation and elimination of carbon dioxide. In addition to this primary function, the lungs have other functions, for example water balance, the maintenance of pH, elimination of inhaled particles and organisms, filtration of particulate matter from the circulation, and metabolism of certain drugs and enzymes. They also serve as a vehicle for the administration of anaesthetic and other drugs. The intimate contact between inspired air (with the multiplicity of organisms, particles and gases that it contains) and the internal epithelium of the lungs (with a surface area some three times that of the body) leads not only to efficient gas exchange but also to repeated opportunities for damage to the lungs and absorption of harmful substances into the body. In order to understand both the normal function of the lungs and the pathology of the diseases with which this book is mainly concerned, it is useful to know something of the development and structure of the organ. In particular, it is now becoming clear that subtle influences on the development of the lung *in utero* and in the early months of extrauterine life may have important effects on lung health in later life, and that the seeds of later chronic airflow obstruction may be sown during the period of intrauterine lung development.

## Development of the lungs

### Development of the airways and vessels

The lung appears first as an epithelial bud at the caudal end of the laryngotracheal groove on the 26th day after ovulation [1,2]. It thus shares its origin with the foregut, reflecting the evolution in our invertebrate ancestors of a respiratory apparatus from the food-sieving mechanism. This bud, derived from endoderm, will form the epithelium of the airways and of the acini. As it elongates, it becomes invested in mesenchyme derived from mesoderm, and this mesenchymal layer exerts control over its

pattern of branching [3]. The mesenchyme itself develops into the connective tissue, cartilage, smooth muscle and vessels of the lung. In the first few weeks of development, nerve fibres arising from the ectoderm migrate into the mesenchyme to give the lung its motor and sensory connections [4]. The developing lung bud divides into two halves and elongates, growing caudally on either side of the oesophagus. By about 33 days the trachea has become separated from the foregut, and pouches representing the five lobes are clearly apparent. Subsequent dichotomous division leads to the development of the full adult complement of segments by 41 days and to completion of the bronchial tree as far as the terminal bronchioles by 16 weeks [5]. While the embryonic lung is developing, changes are also occurring in the circulatory system [6]. The primitive branchial arches come and go, leaving the third to form the carotids, the fourth the aorta and the sixth the pulmonary trunk (Fig. 1.1). This appears at about 32 days, becoming separated from the primitive truncus arteriosus by the development of a spiral septum, and joins the vascular plexus that has already formed in the lung bud. By 37 days, the single ventricle of the heart has divided into two chambers, the blood supply to the lungs coming from the right side. At this stage the right sixth arch artery has disappeared and the lung's main blood supply, the pulmonary artery, comes solely from the left arch. Its branches divide approximately in correspondence with those of the bronchial tree, but so-called supernumerary arteries occur with increasing frequency towards the periphery and supply structures adjacent to the main bronchi. Ultimately they will supply alveoli of neighbouring acini when these have developed. Before the formation of this pulmonary arterial supply, the lung receives its blood from pairs of segmental arteries arising from the aorta above the coeliac axis in the region of the fetal neck. These arteries migrate caudally and eventually disappear, being replaced by new bronchial arteries that arise from the aorta between about 9 and 12 weeks. The persistence of the original primitive bronchial arteries is the explanation for the occasional supply of sequestered

**Fig. 1.1** Development of the pulmonary arteries and aortic arch from the branchial arches.

lung segments by a transdiaphragmatic artery from the aorta above the coeliac axis, a potential hazard well known to thoracic surgeons [7] (Fig. 1.2).

The venous drainage of the developing lungs is initially into the systemic cardinal and postcardinal veins and the visceral veins of the abdomen. These develop into the two venae cavae, the innominate vein and their tributaries. By about 10 weeks a diverticulum arises from the left atrium that connects with those veins draining the lungs, so that the four pulmonary veins finally enter the left atrium. Abnormalities in this development result in anomalous pulmonary veins leading into the vena cava or right atrium or a separate chamber connected to the left atrium, *cor triatriatum* [8]. Drainage of the right lung by an anomalous vein into the inferior vena cava gives rise to the

scimitar sign on the chest radiograph (Fig. 1.3). Thus, by about 16 weeks of intrauterine life, the preacinar structures of bronchi, pulmonary arteries and veins, and bronchial arteries are all present in the numbers and anatomical distribution that they will maintain throughout life. However, important changes are still to occur in these structures at the microscopic level, while they have of course to grow and the acinar structures to develop.

### Cellular development of the lung

Until about 16 weeks, the developing lung has a pseudoglandular appearance, i.e. narrow tubes surrounded by a cuboidal or columnar epithelium on a basal lamina and in a mesenchymal stroma [1,9,10]. By 16 weeks, both goblet cells and mucous glands have developed and ciliated cells are present throughout the bronchial epithelium. From 16 until about 26 weeks the lung's appearance is described as canalicular. The epithelium thins out, the cells becoming flatter and the future air spaces larger. The mesenchyme becomes very vascular, and as the more peripheral airways develop their epithelium becomes very thin, allowing close approximation of blood to the air space. This is a period of rapid growth, during which the lung's DNA doubles [11].

These terminal saccules become well defined towards 26 weeks, when the appearance of the lung is described as saccular. By this time type I and type II pneumocytes can be identified in the saccular epithelium and osmiophilic bodies appear in the type II cells, indicating that the lung has developed the ability to secrete surfactant. This production of surfactant may be promoted by the administration of glucocorticosteroids to the mother in some species [12], a fact that is relevant in improving the survival chances of premature infants. Meanwhile, cartilage, which appears in the trachea at 4 weeks and gradually spreads down the airways to reach segmental bronchi at 12 weeks, has by 26 weeks developed far down the bronchial tree, though further extension occurs until the early weeks of postnatal life. Similarly, smooth muscle, which first appears in the lobar bronchi and above at about 6 weeks, has also spread down to the terminal bronchioles. In the pulmonary arteries smooth muscle appears at about 12 weeks and has reached vessels at the level of the terminal bronchiole by 26 weeks; this vascular smooth muscle will grow further down the arterial tree after birth, reaching alveolar walls in adult life. Thus the lung at about 26 weeks has reached a stage of maturity at which it is capable of supporting life.

The rest of the time spent *in utero*, from 26 weeks to term, is occupied by the development and subdivision of the respiratory bronchioles and their saccules, with a variable amount of alveolar development, and by the growth of the airways. At one time it was thought that there were very few alveoli present at birth, but more recent studies have

**Fig. 1.2** Aortogram showing aberrant arterial supply of sequestered lung segment from aorta.

shown that some alveoli may be present as early as 30 weeks and that as much as 50% of the final adult number may be evident at the time of birth, though this proportion is very variable [13,14].

### **Postnatal development**

At the time of birth there is an adult complement of about 24 million terminal bronchioles [15–17]. From the time of birth there is an initial rapid increase in the numbers and then in size and complexity of alveoli, which start appearing *in utero*, first on the peripheral saccules and then up towards the proximal respiratory bronchioles. Some may even develop on the terminal bronchiole. Some 127 million alveoli are present at about 1 year and most by the age of 2; the final adult complement of about 280 million may have developed by the age of 8, although some authorities suggest that alveolar multiplication continues

at a slower rate until somatic growth ceases, the numbers in adults being estimated to vary between 200 and 600 million. Growth of the airways and modelling of the lung to match the shape of the thorax and its contents continues until the body stops growing. Any abnormality of shape of the thoracic cavity will affect this; for example, a congenital diaphragmatic hernia, when the normal separation of thoracic and abdominal cavities does not occur at 7 weeks, causes a small lung in which the numbers of both airways and alveoli are reduced [18], while kyphoscoliosis developing in early childhood causes a small lung with reduced alveolar numbers [19]. Other important influences on airway or alveolar development are fetal nutrition, which if impaired in mid-gestation may result in smaller or even fewer airways, and oligohydramnios, which may constrict lung growth and lead to smaller airways [20,21]. These influences are currently a matter of considerable research interest to those who wish to understand why one person

**Fig. 1.3** Anomalous vein draining from lower lobe into the inferior vena cava: the 'scimitar' sign.

develops lung disease and another does not when subjected to the same environmental influences in later life. It is clear that some environmental factors, such as poor diet and cigarette smoke, can have an effect at a very early stage in lung development as well as the potential to damage the developed lung.

The most dramatic change in the lung occurs at the time of birth. Fetal breathing movements occur *in utero* and are known to be essential to normal lung development [22], but with the first postnatal breaths the lung inflates and resistance to flow in the pulmonary arteries falls; within a few days the pulmonary pressure has fallen to half systemic pressure. Over the first few weeks the ductus arteriosus and foramen ovale have closed, the small muscular pulmonary arteries have dilated and their muscle coat thinned to adult dimensions, and the pulmonary arterial pressure has fallen almost to its adult level, which it eventually achieves at about 6 months.

## Structure of the respiratory tract

### Upper respiratory tract

The upper respiratory tract is arbitrarily regarded as that part above the cricoid cartilage. It has several important

functions besides air conduction, including swallowing, air conditioning, smell and speech.

### Nose

The nose plays a part in air conduction and conditioning, and clearance of particles and microorganisms [23]. The resistance to airflow in the nose is normally 50% of the total airways resistance and becomes important during exercise (hence the change to mouth breathing in this circumstance) and with nasal obstruction by polyps and rhinitis. The mucous membrane of the nose is lined with ciliated epithelium, which functions in an identical manner to the epithelium of the rest of the respiratory tract in terms of antimicrobial defences. The cilia of the anterior part of the nares, before the turbinates, beat anteriorly and propel mucus and entrapped particles towards the nostrils. From the turbinates backwards, the cilia beat so as to propel particles towards the pharynx. This is made use of in a simple screening test of ciliary function: a small particle of saccharin is placed on the mucous membrane of the inferior turbinate and the subject asked to indicate when the taste is perceived; with normal ciliary function, and in the absence of other nasal or sinus disease, the taste should be noticed within 60 min [24].

The structure of the nose is adapted to its important function of warming and humidification of inspired air [25]. The vascular mucosa and the large surface area presented by the turbinates are important in this respect. Air is heated to approximately body temperature on passage through the nose while its relative humidity is raised to 95%. The lower airways, though able to adapt to the absence of these mechanisms, as in patients with laryngectomies [26], will dry out and become more liable to infection if nose breathing is impossible. This becomes clinically important in patients with tracheostomies or long-term endotracheal intubation, when humidification of inspired air is necessary. During exercise, particularly in cold or dry air, there may be considerable loss of water from the airway vasculature, together with cooling of the bronchial walls. In people with asthma, this may increase the osmolality of the surface lining fluid sufficiently to cause mast cell degranulation and consequent bronchoconstriction [27–29].

Humidification of inspired air is achieved by transudation through the epithelium and, to a lesser extent, by secretion of mucus. Approximately 0.75L of fluid are required for the 10000L of air inspired every 24h. Nervous control of the vascular and glandular mechanisms involved is by the autonomic system.

### Pharynx

The pharynx lies behind the nasal cavities, the mouth and the larynx, ending at the level of the sixth thoracic vertebra where it is continuous with the oesophagus. It is lined in its upper part by ciliated columnar epithelium, which changes through transitional to stratified squamous epithelium over the lower part. The wall is richly endowed with lymphatic tissue, aggregations forming the posterior nasal adenoids and the lingual, eustachian and palatine tonsils. Three circumferential muscles, the superior, middle and inferior constrictors, and two longitudinal muscles, the stylopharyngeus and salpingopharyngeus, complete its wall. Their coordinated action is responsible for swallowing, including prevention of aspiration of food into the trachea. Failure of these mechanisms in patients with bulbar and pseudobulbar palsy and other conditions affecting the vagus and glossopharyngeal nerves is a cause of recurrent pneumonias. The need for the air and food passages to cross over in humans and other mammals is an unfortunate consequence of our evolution from air-breathing aquatic animals.

The inferior pharyngeal constrictor consists of upper oblique fibres and lower circumferential fibres. Between the two is a zone, known as Killian's dehiscence, through which the mucosa may herniate as a pharyngeal pouch. This usually occurs posteriorly, the pouch enlarging downwards and to the left. It causes dysphagia and regurgitation of undigested food and presents a considerable

hazard of perforation to the unwary oesophagoscopist (Fig. 1.4).

Certain patients may have their sleep punctuated by recurrent episodes of apnoea (see Chapter 47). In some of these, the apnoea is due to an obstructive mechanism in the pharynx, whereby the posterolateral walls are invaginated into the lumen during attempted inspiration, possibly due to lack of tonic contraction of the pharyngeal muscles. The pharynx may also be obstructed by the tongue falling backwards in unconscious patients lying supine; nursing such patients on their sides prevents both this and aspiration of regurgitated stomach contents. Finally, posterior pharyngeal carcinomas may present with dyspnoea, due to upper airways obstruction. The respiratory physician should be alert to this as a cause of dyspnoea of relatively recent onset, often associated with stridor.

### Paranasal sinuses and eustachian tube

These structures fall within the realm of the otorhinolaryngologist and are only dealt with briefly here. They are of interest to the respiratory physician in that, sharing a common mucous membrane with the bronchi, they often become inflamed at the same time, for example in allergic conditions. They may also be the source of bleeding that can be mistaken for haemoptysis. The nose is of course the preferred portal of entry for fiberoptic bronchoscopes and prolonged endotracheal intubation.

The paranasal sinuses may play a role in temperature insulation and voice resonance, although their functions are not clear and individuals born with atrophic sinuses seem to come to no harm. The paired maxillary sinuses, between the orbit and the molars, are the largest, with a capacity of about 15mL each. Each has one ostium that opens into the middle meatus between the superior and inferior turbinates. This high position of the ostium makes it liable to accumulate fluid and infections are common, especially in childhood. The ciliated columnar epithelium contains many mucous glands, the cilia sweeping the mucus towards and through the ostium. The maxillary sinus is vulnerable to infection as a result of facial injuries, dental sepsis and barotrauma. The frontal sinuses, above the orbits, drain inferiorly into the middle meatus, while the ethmoid and sphenoidal sinuses drain into the superior and middle meatuses. These structures are all liable to be affected by respiratory tract infections and allergy. In addition, the rare adenocarcinoma of the nasal sinuses may be a consequence of exposure to inhaled carcinogens in the workplace [30,31]. Wegener's granuloma is another nasal condition that may occur in association with lung disease (see Chapter 40).

The eustachian tube connects the middle ear to the pharynx. It is about 4cm in length and is normally collapsed, opening during yawning and swallowing as a

**Fig. 1.4** Barium swallow showing large pharyngeal pouch that caused dysphagia and aspiration pneumonia.

result of the action of the tensor veli palatini muscle [32]. It assumes importance during diving and aviation, when active expiration against a closed nose is necessary to equalize pressures between throat and ear (see Chapter 57). Inability to do this, due to infection or mucosal oedema, may result in trauma to the ear-drum. A pressure of about 4.0 kPa (30 mmHg) is required to open the tube [33].

### Larynx

The respiratory physician must have some knowledge of the larynx because intrinsic laryngeal disease sometimes

presents as airways obstruction with wheeze and dyspnoea and also because involvement of the recurrent laryngeal nerve may make voice changes the first sign of serious intrathoracic disease. The larynx consists of three articulating cartilages, the thyroid, cricoid and arytenoid [34]. The vocal cords pass from the arytenoids posteriorly to the thyroid anteriorly. They are tensed by the action of the cricothyroid muscles, which pull the thyroid cartilage anteriorly and downwards (Fig. 1.5), while they are abducted by rotation of the arytenoids by the posterior cricoarytenoid muscles. The transverse arytenoids and lateral cricoarytenoids are responsible for adduction of the cords. When examining the larynx, abduction can be seen

**Fig. 1.5** The cricothyroid muscles pull the thyroid cartilage anteriorly and downwards, thus tensing the cords.

to occur on inspiration. Adduction occurs on phonation, the usual practice being to ask the patient to say 'eeeeee'. All the intrinsic muscles of the larynx except the cricothyroids are supplied by the recurrent laryngeal nerves. Injury to these nerves therefore prevents abduction or adduction, the cords lying in a neutral position. Bilateral paralysis, which may occur as a result of thyroid carcinoma or following thyroidectomy, causes fixation of both cords and therefore a seriously compromised airway. If the damage to the nerves is incomplete the result can be life-threatening, as the abductors tend to be paralysed before the adductors. More usually, unilateral paralysis occurs as a result of tumour, or occasionally fibrosis or surgery, and one cord is then fixed (Fig. 1.6). The cricothyroid muscles are supplied by the superior laryngeal nerves. If they are paralysed, as may occur following thyroidectomy, the cords are unable to be tensed.

All the laryngeal nerves derive from the vagus, which therefore also carries sensory messages from the laryngeal mucosa. Combined paralysis of superior and recurrent nerves may occur as a result of lesions of the medulla oblongata, such as poliomyelitis and syringobulbia, tumours involving the vagus at the brainstem and lesions of the thyroid gland. The most common paralytic lesion seen is that due to damage to the left recurrent laryngeal nerve, which leaves the vagus at the level of the aortic arch, hooks round the aorta and ligamentum arteriosum and runs up the mediastinum between trachea and oesophagus, deep to the thyroid, to reach the larynx beneath the lower edge of the inferior pharyngeal constrictor muscle. This long intrathoracic course makes the nerve vulnerable to involvement by pulmonary and other neoplasms around the aortic arch, as well as by the much rarer aortic aneurysm. Involvement of the nerve

**Fig. 1.6** Left recurrent laryngeal nerve palsy with immobile left cord: (a) on inspiration, right cord abducts; (b) on phonation, right cord crosses the midline.

in fibrosis, either idiopathic or following drugs (such as practolol), tuberculosis or radiotherapy may occasionally cause paralysis. The right recurrent nerve has a much shorter course, arising in the neck at the level of the subclavian artery which it hooks round before passing up deep to the thyroid. Either nerve may be affected by tumour in the cervical lymph nodes or at the thoracic inlet, by thyroid carcinoma, aneurysm or surgery on the thyroid gland. Anaesthesia of the larynx, as during fiberoptic bronchoscopy, may paralyse the superior laryngeal nerves, causing lax cords.

Apart from neurological dysfunction, the larynx may be affected by other conditions that cause symptoms resulting in referral to chest physicians. Carcinoma of the larynx may present with breathlessness and hoarseness, as may rheumatoid disease of the cricoarytenoid joints. Laryngeal tuberculosis and syphilis are now rarities, but damage to the cords by prolonged or inexperienced intubation may occur.

The usual symptom of left recurrent nerve paralysis is hoarseness and loss of voice power. Since adduction of the cords is required for the explosive component of cough, this is lost and the cough is described as bovine. As time passes, the contralateral cord may be able to compensate for unilateral paralysis and the voice and cough may recover. If this does not occur, injection of Teflon into the paralysed cord can bring it closer to the midline and allow closure to be more complete. Bilateral cord paralysis usually causes inspiratory stridor and breathlessness. Characteristic impairment of peak expiratory and inspiratory flow rates occurs, causing a rounded flow-volume curve (see Chapter 2). Hysterical aphonia may sometimes be seen and in such cases the cords appear unable to adduct; however, pure adductor paralysis does not occur as a neurological lesion and if the patient can be persuaded to cough the cords can be seen to approximate to each other.

Benign tumours of the larynx may be found incidentally at bronchoscopy and may sometimes be the only explanation for haemoptysis; these include fibro-angiomatous polyp and laryngeal granuloma. The latter is usually due to previous intubation. Singer's nodules on the cord are organized haematomas that are presumably due to vocal trauma. Sarcoidosis, Wegener's granuloma and relapsing polychondritis, as well as rheumatoid disease, may also affect the larynx. For a detailed account of the structure, function and pathology of the larynx, the reader is referred to the review by Proctor [34].

## Lower respiratory tract

### Trachea

The trachea extends from the larynx, which fixes it through the hyoid bone to the skull, down to its bifurcation in the mediastinum at the level of the fifth thoracic vertebra [34]. At its lower end it is anchored to the mediastinum by the two main bronchi and by oblique connective tissue fibres running to the dorsal surface of the pericardium. The bifurcation is displaced slightly to the right of the midline, and the trachea runs postero-inferiorly from its origin, only usually being superficial over its first few centimetres. Its length varies with movements of the head and respiration but averages about 10–12 cm in the adult. Its extrathoracic portion extends down to the sixth cartilage and is closely related to the thyroid gland laterally and its isthmus anteriorly. The recurrent laryngeal nerves also run laterally, beneath the thyroid, while the oesophagus is directly behind, separating it from the vertebrae. The lower half of the trachea is intrathoracic, and thus lesions causing its narrowing may have different physiological effects depending on their site. In general, extrathoracic narrowing causes predominant inspiratory obstruction and reduction of peak expiratory flow rate, whereas intrathoracic obstruction causes mainly expiratory obstruction (see Chapter 2). As it enters the chest, the trachea is related anteriorly to the remains of the thymus, the left innominate vein, the right innominate artery and the left common carotid artery. A retrosternal extension of the thyroid may occasionally compress it at this point (Fig. 1.7). To its right are the innominate vein, superior vena cava and azygos vein, while on its left lies the aortic arch. The left recurrent laryngeal nerve runs up between the aortic arch and trachea and then in the ridge between the trachea and oesophagus, where it may be involved by neoplastic nodes from bronchial or oesophageal tumours. At its lower end the trachea divides into the right and left main bronchi. The ridge between the bronchi seen through the bronchoscope is the carina. It normally narrows on inspiration but may be widened by enlarged mediastinal nodes or by a dilated left atrium. The former may be subjected to transtracheal needle biopsy at this point.

**Fig. 1.7** Chest radiograph showing severe compression of the trachea by the retrosternal thyroid. The patient presented with stridor.

The trachea is oval in cross-section, being slightly longer in transverse than in sagittal diameter. It is lined with a mucous membrane of pseudostratified, ciliated, columnar epithelium containing goblet cells. There is a submucosa containing elastic fibres arranged in longitudinal bands and also connected to circular fibres in the fibrocartilaginous layers. A capillary plexus and mucous glands are also found in the submucosa. The tracheal cartilages are semicircular, the gap being in the posterior part where the circle is completed by a 'membranous' portion. Smooth muscle connects the posterior tips of the cartilage, its contraction resulting in narrowing of the trachea and stabilization of its otherwise easily invaginated posterior wall. The cartilages are connected to each other by fibrous tissue extending from their perichondrium.

The trachea is mobile, being pulled as much as 3 cm at the top and 1 cm at the bifurcation on swallowing. Inspiration causes caudal stretching of the trachea as well as movement anteriorly from the vertebral column. This limited mobility may be enhanced by the thoracic surgeon during tracheal reconstruction, e.g. after resection of strictures or tumours, by division of its inferior connections with the pericardium and mediastinum.

## Bronchi and their divisions

### Gross anatomy

The trachea divides into right and left main bronchi [35]. The left runs more horizontally than the right, above the left atrium. It is about 5 cm long and is related to the aortic arch above, the descending aorta and thoracic duct posteriorly, and the left pulmonary artery anteriorly then superiorly. The right main bronchus, being a more direct continuation of the trachea, is the more usual path for inhaled foreign bodies. It is only about 1–2.5 cm long; the right pulmonary artery runs below then anterior to it, while the azygos vein arches over it superiorly. The right main bronchus divides into the right upper lobe bronchus, which in turn divides into anterior, apical and posterior segmental bronchi, and the bronchus intermedius. This latter gives off middle lobe and apical lower lobe bronchi, then divides into the four basal segmental bronchi: anterior, medial (cardiac), posterior and lateral. The middle lobe bronchus divides into medial and lateral segmental bronchi. The left main bronchus gives off upper and lower lobe bronchi; the upper lobe bronchus divides into apico-posterior and anterior segmental bronchi and a lingular bronchus that in turn divides into superior and inferior bronchi. The left lower lobe bronchus gives off an apical bronchus and then divides into anterior, lateral and posterior segmental bronchi. There is no left medial basal segmental bronchus.

The usual pattern of bronchial branching is shown in Fig. 1.8. However, anomalous bronchi are relatively frequent [36,37]; subapical bronchi in the lower lobes and a bronchus arising from the trachea to supply the apical segment of the right upper lobe are not infrequent examples. Details of variations in segmental anatomy have been given by Boyden [36] and bronchoscopic illustrations by Stradling [38].

The trachea, main bronchi and lower lobe bronchi are outside the lung substance. All other bronchi are situated within the lung, and as they enter it they take with them an invagination of the visceral pleura, forming a peribronchial sheath separated from the bronchi by a potential space.

The lower airways are known as bronchi down to the smallest divisions containing cartilage, however sparse. Thereafter they become bronchioles, the final branch of this type being the terminal bronchiole. Subsequent divisions contain increasing numbers of alveoli in their walls and are called respiratory bronchioles; these give off the alveolar ducts and the air sacs and alveoli. The ultimate lung unit from each terminal bronchiole is called the acinus. From the tracheal bifurcation the smallest bronchi are reached after some 8–13 divisions, depending on the area of lung supplied. There is variation depending on the size and shape of the segments; for example, in the apical

**Fig. 1.8** Segmental bronchi: (a) anterior, (b) right lateral and (c) left lateral. Upper lobes: 1, apical; 2, posterior; 3, anterior; 4 and 5, superior and inferior lingular branches (left only). Middle lobe: 4, lateral; 5, medial branches. Lower lobes: 6, apical lower; 7, medial (right only); 8, anterior; 9, lateral; 10, posterior branches. (After Brock [37].)

lower segment, where the bronchi run a relatively short course, the terminal bronchioles may be reached after 15 generations from the origin of the segmental bronchus, whereas in the lingula it may be 25. There tend to be fewer generations in lateral than in axial branches [39]. From the smallest bronchi, which are about 1 mm in diameter, there are about three to four further subdivisions of bronchioles before the terminal one is reached. There are about 25000 terminal bronchi, each of which divides dichotomously into respiratory bronchioles [35]. There are usually two subsequent divisions of respiratory bronchioles, the more peripheral branches bearing more alveoli, and a final division into alveolar ducts, which are completely surrounded by alveoli. Up to nine generations of alveolar ducts occur before the alveolar sacs arise as the terminal unit of the airways. There are thus about 28 orders of division of the tracheobronchial tree. The total number of alveoli has been estimated to be between 200 and 600 million [40,41].

### Total cross-sectional area of the airways

The total cross-sectional area of the airway in the trachea is about  $2\text{ cm}^2$ , and this does not increase in the first one or two divisions. Thereafter, increasing division produces a greater area, estimated to be about  $14\text{ cm}^2$  after 14 orders,  $80\text{ cm}^2$  at the level of the terminal bronchiole and  $700\,000\text{ cm}^2$  at the level of the alveolar ducts [42]. Thus maximum resistance to airflow occurs in the large airways. This fact, coupled with the observation that much of the damage associated with cigarette smoking can be found in small airways (often arbitrarily defined as those  $2\text{ mm}$  in diameter or less), has led to a search for tests of small airways obstruction that will allow early detection of smoking-associated airways disease (see Chapter 2). However, these estimates do not take account of the asymmetry of bronchial branching, longer parts of the bronchial tree having more divisions than shorter ones. Thus a more accurate model of total cross-sectional area against distance from the trachea would imply a diminution in total area beyond the maximal point [35,43] because of the progressively smaller numbers of bronchioles in the more distal parts of the lung (Fig. 1.9).

### Segmental anatomy

The lobes of the lung are divided into segments corresponding to the segmental bronchi. These segments repre-

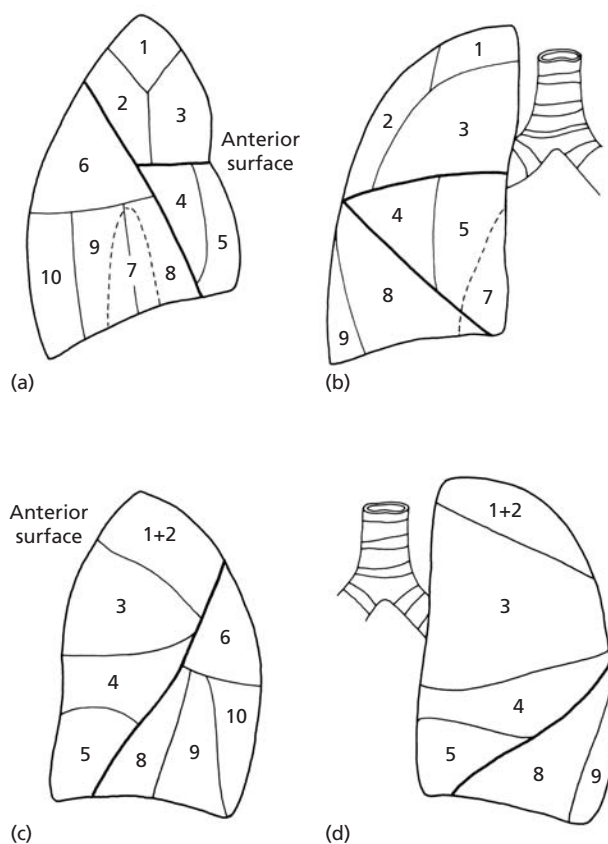

**Fig. 1.9** Model of total cross-sectional area of airways from carina to periphery, taking account of different lengths of bronchi. (From Horsfield [35].)

sent units that can usually be distinguished by the surgeon and removed without dividing other major vessels or bronchi. However, they are not completely separated from each other, being divided partially by fibrous septa peripherally. Occasionally, infoldings of pleura into partial fissures between segments may be seen radiologically. The segments may further be distinguished by branches of the pulmonary veins, which run between them. Segmental division of the lungs is variable, and the most frequent arrangements are shown in Fig. 1.10.

In about 0.25% of right lungs, the so-called azygos lobe may be seen radiologically. This is a developmental anomaly caused by the azygos vein looping over a portion of the apical segment of the upper lobe rather than directly over the right main bronchus. This causes an infolding of the pleural layers, which shows as a thin outwardly convex line ending in an oval shadow below, the latter representing the azygos vein. There is no associated abnormality of bronchial anatomy.

A sequestered segment is a part of the lung that has become isolated during development [44,45]. Its bronchi, which are usually cystic and dilated, do not connect with the bronchial tree, while its blood supply is derived from

**Fig. 1.10** Segmental anatomy of the lung: (a) right lateral, (b) right anterior, (c) left lateral and (d) left anterior. For explanation of numbers see Fig. 1.8.

Fig. 1.11 Cross-section of a large bronchus.

the aorta, occasionally through the diaphragm. It is most common in the lower lobe, especially on the left. It may cause problems by becoming infected (see Chapter 50).

#### *Microscopic anatomy of the airways*

The bronchial walls contain three layers, the mucosa, sub-mucosa and fibrocartilaginous layer, the latter including the smooth muscle [46] (Fig. 1.11).

#### *Mucosa*

The mucosa has now been shown to be a true stratified, rather than pseudostratified, squamous epithelium set on an elastic lamina. Basal cells are attached to the lamina by integrin molecules, and these contribute to the desmosomes that are responsible for adhesion of columnar cells to the basal cells [47]. In the inflammation characteristic of asthma, the mucosa splits off between basal and columnar cell layers [48]. The mucosa thins progressively as it becomes more peripheral, finally merging with the flat epithelium of the alveoli. Flat areas of unciliated squamous epithelium occur over the proximal carinae, but most of the mucosa is covered by groups of ciliated cells interspersed with polygonal non-ciliated Clara cells, joined at the epithelial surface by tight junctions. Eight different cell types have been described in the human bronchial epithelium.

The *ciliated cell* has approximately 200 cilia, each between 5 and 10  $\mu\text{m}$  in length [49]. Microvilli occur between the cilia. The epithelium contains some 1500–2000 cilia/ $\text{cm}^2$ , although the cells become more sparse in peripheral airways. The cilia beat about 1000 times per minute, always with an active stroke in the direction of the oropharynx, followed by an inactive recovery stroke (Fig. 1.12). The net effect is to convey bronchial secretions towards the pharynx whence they

Fig. 1.12 Mechanism of ciliary beat: effector stroke (solid line) moves raft of mucus towards pharynx; recovery stroke (broken line) reduces risk of reverse movement.

can be swallowed or coughed up [50]. Under the electron microscope, the tip of the cilium has been observed to have small claws that protrude into the mucus on the active stroke, helping to propel it [46]. In cross-section the cilium shows an almost identical ultrastructure regardless of whether it is on a bronchial epithelial cell, a flagellate protozoon, a fish gill or a spermatozoal tail [51] (Fig. 1.13).

The shaft consists of longitudinal fibrils in a cytoplasmic matrix. There are nine paired outer fibrils and two inner ones. These fibrils are specialized protein microtubules. The peripheral nine pairs each consist of one complete and one partial microtubule. Adjacent pairs are connected by so-called nexin links, while the outer fibrils are connected to the central pair by radial spokes. These linking structures are proteins, like the microtubules themselves. From each of the complete outer microtubules two arms extend towards the adjacent pair. These are known as dynein arms and consist of an ATPase protein. From the base of each cilium, the peripheral tubules extend some short distance within the cell, where they connect the cross-striated root fibres that anchor the cilium more deeply into the cell. A laterally projecting foot also connects with the base of the tubules, extending in the direction of the active stroke.

**Fig. 1.13** (a) Cross-section of a cilium: the nine outer microtubule doublets and two central single microtubules are linked by dynein arms, nexin links and spokes. (After Afzelius & Mossberg [52].) (b) Electron micrograph of cross-section of normal cilia ( $\times 44\,000$ ).

Bending of the cilium appears to result from an active sliding movement between adjacent pairs of tubules, powered by an ATP-dependent shearing force developed by the dynein arms linking them. The short, rapidly beating cilia of bronchial epithelium are well adapted to the transport of mucus floating on a layer of watery fluid. The cilia of an individual cell beat synchronously, while there is a degree of coordination between adjacent cells in that those at right angles to the effective stroke beat synchronously and those parallel to it beat in sequence. This results in the propagation of a wave over the ciliary surface (metachronism). Many of the studies of cilia have been carried out on cells from other species and it seems likely that metachronism is somewhat less well developed in mucus-carrying systems than in those systems responsible for propulsion of the organism.

Recent evidence suggests that ciliated epithelial cells may have a secretory function in the airway inflammation characteristic of asthma [53]. Expression of interleukin (IL)-1, IL-6 and IL-8 may play a part in attraction and proliferation of T lymphocytes, while granulocyte-macrophage colony-stimulating factor may be produced and activate eosinophils. Transforming growth factor  $\beta$ , a cytokine with immunomodulatory and tissue homeostatic roles, has been demonstrated in these cells [54], as has another cytokine, endothelin, which may be produced by

asthmatic epithelium [55] and which is able to stimulate mucus production and to cause proliferation of smooth muscle. Epithelial cells have also been shown to produce an as yet uncharacterized factor, which relaxes smooth muscle, and nitric oxide (NO), which has similar effects [56].

Although nerves have been observed in relation to ciliated cells, it is thought that the cilia of the respiratory tract are not under nervous control; their frequency of beating seems to be affected by cellular metabolism, and probably by mechanical stimulation and by drugs that influence metabolism.

The *goblet cell* is responsible for the secretion of mucin. It is present in large numbers in the proximal airways and becomes more sparse in the peripheral bronchi and bronchioles. It contains large, electron-lucent secretory granules and an irregular basal nucleus [49].

The *Clara cell* is most profuse in the bronchioles and distal bronchi. It bulges above the ciliated cells into the airway lumen and has a secretory function [57,58]. It has an irregular nucleus, an abundant smooth endoplasmic reticulum and mottled secretory granules at the luminal end. These cells, like type II alveolar cells, produce surfactant-associated glycoprotein [59]. It has been suggested that this cell may be a progenitor of atypical alveolar epithelial hyperplasia and adenocarcinoma [60].

The *serous cell* is another secretory cell, also with an irregular nucleus, but with small, very electron-dense granules and a rough endoplasmic reticulum. Microvilli are present on the surface. It is more frequently observed in fetal airways and it is possible that it can transform into the goblet cell as a result of irritation [46].

*Basal cells* are small conical cells on the basement membrane that are overlapped by the ciliated and secretory cells. They are undifferentiated cells with the potential to develop into the more specialized epithelial cells [46] and, as mentioned above, express adhesion molecules [47]. Basal cells are found mainly in bronchi and infrequently in bronchioles.

*Intermediate cells* are more elongated than basal cells and may reach the airway lumen [49]. They have microvilli on their surface but have not yet acquired cilia or secretory granules. They are found equally in central and peripheral airways and represent another undifferentiated precursor cell.

*Brush cells* occur throughout the airways [61]. They have a well-marked surface covering of microvilli up to 2 µm in length. It is thought, by analogy with intestinal cells, that they have a fluid absorptive function.

The *endocrine cell* (also called Kulchitsky, Feyrter or APUD cell) is basally situated in main to subsegmental bronchi [62], and is the cell from which both carcinoid and oat cell tumours may arise [63]. These cells contain many small electron-dense granules, which have been shown to contain 5-hydroxytryptamine (5-HT) and a range of other bronchoconstrictor and vasoactive substances [64]. Increased numbers and degranulation are found in association with hypoxic conditions, suggesting that they have a role as chemoreceptors [65]. This is supported by the finding that groups of these cells may be supplied by nerves, when they have been called neuroepithelial bodies [66]. They may also play a part in the airway response to inhaled allergen by release of their mediators [67].

### *Submucosa*

The submucosa is a thicker layer external to the basement membrane and contains elastic fibres, mainly in longitudinal bundles but also connected with the mucous membrane and with the circular fibres of the fibrocartilaginous layer. In addition the submucosa contains mucous glands, smooth muscle, nerves and lymphatics. Mucous glands are most numerous in medium-sized bronchi. In the large bronchi they are situated between mucosa and cartilage, but often extend out between the cartilage. They may lie external to the muscle with their ducts passing through it. Mucous glands are the main source of bronchial secretion and contain both mucous and serous cells. The glands consist of a ciliated duct, which communicates with the airway lumen, a wider collecting duct and mucous and serous secretory tubules. In general the serous tubules are more distal, forming buds off the mucous tubules [68], and are lined by serous cells containing small electron-dense granules [69], which secrete neutral glycoprotein, lysozyme and lactoferrin. The serous cells are joined by tight junctions, although intercellular canaliculi occur. The mucous cells contain larger, electron-lucent granules that

aggregate together [69]; they secrete acid glycoprotein. The collecting duct is lined by columnar cells with densely packed mitochondria, thought by some to have a role in fluid regulation, while the ciliated duct has an epithelium similar to that of the airway. In addition to these cells, lymphocytes and plasma cells, which are probably responsible for the production of IgA [70], and myoepithelial cells, which are thought to be contractile and to aid transport of secretions out of the gland, are found in the bronchial mucous gland. Unmyelinated nerves supply all parts of the gland and the myoepithelial cells. Capillaries are found especially around the collecting duct.

The mucous glands may be up to 1 mm in length. Chronic airway irritation by cigarette smoke or dust results in increased numbers of glands and also increase in their size [71]. This enlargement appears to be due to hyperplasia (increased numbers of cells) rather than cellular hypertrophy [72]. Enlargement of the lumina of acini is probably related to increased amounts of secretion.

### *Fibrocartilaginous layer*

The airway smooth muscle in the trachea and main bronchi is arranged mainly in transverse bundles connecting the posterior ends of the cartilages. Contraction here brings the tips of the cartilage plates together, causing the mucous membrane posteriorly to bulge into the airway lumen. Fine longitudinal bundles of smooth muscle also occur outside the transverse band. Passing further down the airways, the transverse muscle is inserted further anteriorly on the cartilages and eventually becomes a complete ring. The fibres also pass more obliquely, forming spirals to both left and right that branch and interconnect resulting in a geodesic network. Contraction of muscle within the intrapulmonary airways down to the respiratory bronchioles therefore results in narrowing and shortening of the airways. In pathological states, such as asthma or anaphylaxis, the narrowing can completely occlude the airway. The thickness of muscle relative to the airway wall is greatest in terminal bronchioles and reduces more peripherally, although muscle bundles can still be seen in the walls of alveolar ducts.

The bronchial muscle has resting tone, which may be demonstrated by a reduction in airway resistance and increase in anatomical dead space after inhalation of sympathomimetic agents or parasympathetic antagonist drugs. In addition, airways narrow and shorten on expiration. This muscular tone may be increased by inhalation of irritants, histamine and 5-HT, parasympathetic agents and prostaglandin  $F_{2\alpha}$ . Hypoxia, hypocapnia and possibly hypercapnia also cause muscular contraction. Relaxation of tone occurs with lung inflation and sympathetic and vagolytic drugs. The larger the airways, the greater the anatomical dead space (i.e. the volume of air in the respiratory tract not in contact with alveoli) and therefore the

greater the respiratory work necessary to maintain a given alveolar ventilation rate. On the other hand, constriction of the airways increases their resistance to airflow, the resistance increasing inversely in proportion to the fourth power of the radius. Thus there must be an optimum anatomical dead space for a given alveolar ventilation rate; for quiet breathing this has been calculated to be about 125 mL.

The fibrocartilaginous layer continues from the trachea, with its horseshoe-shaped cartilages, down to the smallest bronchus. Bronchioles, by definition, contain no cartilage. In the intrapulmonary airways the cartilage becomes arranged in plates, connected to each other by a fibrous layer consisting of longitudinal bundles of collagen and elastin. The plates of cartilage become smaller and sparser further down the airways and the fibrous layer becomes thinner, eventually merging with the connective tissue of the lung and the fibrous framework around the alveolar ducts. Nerves, blood vessels and mucous glands pierce the fibrous layer on their way to and from the submucosa and mucosa.

#### *Mast cells*

Mast cells may be found occasionally in the bronchial submucosa and mucosa. They assume importance in asthma, where they are a major source of mediators of bronchial inflammation and smooth muscle contraction [73]. They are morphologically similar to the circulating basophil, containing an inconspicuous nucleus and dense basophilic granules. The latter are about  $0.5\mu\text{m}$  in diameter and surrounded by a membrane. In asthmatic airways the granules may disappear, indicating release of mediators. They may also be relevant to bronchiolo-alveolar inflammation in syndromes of pulmonary fibrosis, where they have been found in excess numbers in lavage fluid [74].

#### *Secretions of the airways*

The secretions of the airways [75,76] are familiar to the clinician as sputum. However, this substance is the product of an abnormal bronchial tree and may differ both qualitatively and quantitatively from the normal bronchial secretions. Sputum is a mixture of bronchial secretions, cells and cellular debris, cleared organisms and saliva. The bronchial secretions themselves, even in normal airways, are contaminated by surfactant from alveoli and by fluid transudate. The bulk is secreted by the serous and mucous cells of the bronchial glands, with important contributions from the goblet cells of the bronchial epithelium as well as from the serous and Clara cells.

Mucus is present over the bronchial epithelium as a continuous sol layer, in which the cilia beat, and a gel layer,

which at bronchiolar level appears as distinct rafts floating on the sol layer; these gradually merge together to provide an almost complete covering of the epithelium in the larger airways. The depth of the sol layer is probably about  $5\mu\text{m}$ , just sufficient to cover the cilia during their effective stroke so that the gel layer is propelled over the surface. While the gel layer is clearly secreted by the mucous glands and goblet cells, the sol layer is probably derived largely from the Clara cells with some contribution from transudated fluid.

The watery sol layer has been shown to contain albumin, lysozyme, immunoglobulins,  $\alpha_1$ -antitrypsin,  $\alpha_1$ -antichymotrypsin and glycoprotein, with very little lipid. The gel layer, which forms the bulk of mucoid sputum produced by the bronchitic patient, contains 95% water, protein, carbohydrate and lipid (about 1% each) and DNA and electrolytes. The proteins are mainly complex polydispersed glycoproteins called mucins, which give mucus its characteristic physical properties, and immunoglobulins, especially IgA. The glycoproteins of mucus have a high molecular mass ( $1.5\text{--}2\times 10^6$  kDa), with a long protein core and carbohydrate side-chains, of which the main ones are galactose, *N*-acetylglucosamine and *N*-acetylgalactosamine. The glycoproteins may be neutral or contain sialic acid or sulphate. These long molecules are organized into fibrous strands connected by cross-bonds of hydrogen and disulphide, the whole structure being responsible for the viscoelastic properties of mucus.

The functions of bronchial mucus include waterproofing, thus diminishing water loss from the respiratory tract; protection of the epithelium, by forming a barrier between it and particles in the inhaled air; and defence, by removal of inhaled particles as a result of ciliary activity, and by acting as a vehicle for immunoglobulins.

The two most characteristic physical properties of bronchial mucus are its viscosity and elasticity [77]. Viscosity is a measure of a fluid's resistance to flow, whereas elasticity is a measure of a solid's ability to store applied energy in order to return to its original shape after a deforming force has been removed. In terms of bronchial clearance, the viscosity of mucus allows the cilia to engage it during their effector stroke (which proceeds relatively unimpeded through the non-viscous sol layer) and to stretch it, because of its elasticity, in an upwards direction. The elastic properties of mucus also allow it to transfer the energy imparted by the cilia to the transport of particles caught upon its surface. Experiments using *in vitro* mucociliary systems have shown that both viscous and elastic properties are important in mucus transport and that there is an optimal value for each beyond which transport is less effective.

IgA is an important component of bronchial mucus. It is secreted originally by lymphocytes and plasma cells in the

bronchial glands [70], probably as the monomer that is also found in serum. In the course of passage through the gland, two IgA molecules are linked by a peptide known as secretory piece to form the dimer, secretory IgA [78,79]. It is not known whether this conjugation occurs within cells or in the gland lumen. It then becomes incorporated into the glycoprotein structure of the bronchial mucus, probably by hydrogen or disulphide bonding. It is able to protect the mucous membrane by forming complexes with proteins, such as those of bacteria, and also plays a role in increasing the strength and stability of the mucus itself.

Many other proteins are found in bronchial secretions. It is likely that their presence depends on passive diffusion from the blood, as in general the ratios of their concentration in sputum to that in serum are in inverse proportion to their molecular weights. However, qualitative studies of the constituents of bronchial secretions are complicated by considerable technical problems [80,81]. Water is, of course, the major component of bronchial secretions. Since the sol layer provides a continuous covering for the distal airways, with their considerable total surface area, one of the functions of the airway epithelium must be to reabsorb much of this fluid as it passes upwards. The brush cells may serve this function.

## Acinus

### General structure

The acinus is that part of the lung distal to the terminal, non-alveolated bronchiole [42]. It thus consists of up to three orders of respiratory bronchioles, each with alveoli arising from its walls, usually three but up to nine generations of alveolar ducts, terminal alveolar sacs and alveoli. The terminal bronchiole and the respiratory bronchioles usually divide dichotomously, but three or more divisions may occur in alveolar ducts. Alveoli arise relatively infrequently from the first respiratory bronchiole and more profusely subsequently, so that alveolar ducts are in fact very short tubes surrounded almost entirely by the orifices of alveoli, while alveolar sacs are even shorter, hemispherical structures, the walls of which are composed of alveoli. There are approximately 25 000 acini in the human lung, giving rise to some 300 million alveoli. The total surface area of the alveoli has been estimated to be between 40 and 80 m<sup>2</sup>.

The walls of the respiratory bronchioles contain some muscle bundles, diminishing in amount peripherally, and muscle fibres may also be present between the orifices of alveoli that branch off the alveolar ducts. Muscle and collagen fibres, reticulin and elastin form the supporting structure of the alveolar ducts. The epithelium of the respiratory bronchioles away from the alveolated portions is cuboidal and contains the same cells as the more proximal

airways, with ciliated and Clara cells prominent. The alveolar epithelium is flattened and composed largely of the very thin type I pneumocyte and the more cuboidal type II pneumocyte (see below). Each respiratory bronchiole is accompanied on one side by a muscular pulmonary artery, and this side is devoid of alveoli. The vessel gives off arteriolar branches that in turn supply the capillaries to alveoli. Each alveolus is surrounded by a network of capillaries with very thin walls composed of endothelial cells. The alveolar wall thus consists of a layer of alveolar epithelial cells, their basement membrane, a thin interstitial space that may contain small amounts of collagen and elastin, unmyelinated nerves and occasional macrophages, the capillary basement membrane and capillary endothelial cells [82]. In many places the basement membranes fuse, thus eliminating the interstitial space and minimizing the distance for gas diffusion from alveolar space to red blood cell to about 0.2 µm at its narrowest.

The alveolar capillaries join together to form venules, alongside the respiratory bronchioles, that in turn merge into pulmonary veins. These vessels, in contrast to the pulmonary arteries, do not run alongside bronchi but in the interlobular septa. These septa are connective tissue divisions between what are known as *secondary lung lobules*. They separate groups of between three and five terminal bronchioles and their acini from each other and are easily visible as the smallest segment of lung bounded by connective tissue when a slice of lung is examined with the naked eye. Lobules also represent that part of the lung where airway branching changes abruptly from a frequency of one every 0.5 cm to one every 2–3 mm. Care should be exercised with this terminology, since a *primary lobule* is defined as an alveolar duct and its distal connections.

Ventilation of alveoli may occur via collateral pathways as well as directly down the bronchiolar tree [83]. Small (10–15 µm) openings in alveolar walls, known as pores of Kohn [84], allow gas to pass between adjacent alveoli, even from adjoining segments. These pores have not been observed in the prenatal lung and appear to become both more profuse and larger throughout life [85]. In addition to these pores, short bronchiole–alveolar communications lined with epithelium [86] allow gas to pass from one bronchiole to alveoli of a neighbouring acinus. They are about 30 µm in diameter and many remain open regardless of the degree of bronchiolar smooth muscle constriction elsewhere. There is also evidence that larger diameter interbronchiolar communications may occur between adjacent respiratory bronchioles [87]. It is likely that collateral ventilation also occurs at the level of alveolar ducts [88].

### Alveolar wall

The alveolar wall consists of types I and II pneumocytes,

basement membranes, interstitial tissue and capillary endothelial cells [82]. The interstitial tissue contains some bundles of elastin and collagen, nerve fibres and nerve endings. It is normally only 5–10 µm in diameter. Macrophages may be found in the interstitial space as well as in the alveolar or airway lumens.

#### *Type I pneumocytes*

Type I pneumocytes are the pavement epithelium of alveoli, specialized for the diffusion of gas from alveolus to capillary. Although fewer in number than type II cells, their surface area is much greater as they are extremely flattened; they thus cover most of the alveolar surface (Fig. 1.14). Under the electron microscope they can be seen to contain pinocytic vesicles. Type I cells are connected to each other by tight junctions, which prevent leakage of fluid into the alveolar lumen. They are derived from type II cells and do not themselves undergo mitosis [89]. There is evidence that they are able to transport fluid, small molecules and dust particles from the alveolar lumen by pinocytosis [90].

#### *Type II pneumocytes*

Type II pneumocytes are more numerous than type I cells. They are cuboidal in shape and have microvilli on their alveolar surface. They tend to be grouped in the corners of the alveoli. The cytoplasm is rich in mitochondria and endoplasmic reticulum and also contains characteristic vacuoles containing osmophilic lamellar bodies (Fig. 1.15). These are secreted into the alveolar lumen as surfactant [91]. The type II cell is also the precursor of type I cells, a role that can sometimes be observed in acute alveolar injury, when type II proliferation takes place and intermediate cells may be seen [89]. With chronic injury, the alveoli may become lined exclusively with proliferating type II cells. It is also likely that these cells have a role in secreting components of the basement membrane [92].

#### *Endothelial cells*

Endothelial cells line the alveolar capillaries and are the most numerous of the alveolar cells. Unlike the epithelial cells, they are not connected by tight junctions and thus allow small molecules and fluid to escape. The most notable ultrastructural feature of endothelial cells is the presence of pinocytic vesicles. Where these meet the luminal surface they form caveolae, which appear to be separated from the lumen by a fine membrane. The walls of the caveolae are sites of intense enzymatic activity; 5-HT and prostaglandins are degraded here and angiotensin-converting enzyme is present also. The luminal surface of the capillary endothelial cell is relatively smooth, while that of more proximal vessels tends

to have protrusions, especially at the margins of the cells [93]. Endothelial cells are the primary lung source of the smooth muscle relaxing factor, NO [94]. This radical, produced by the action of nitric oxide synthetase on L-arginine, acts on smooth muscle by increasing the levels of cyclic GMP. It is an important natural pulmonary vasodilator.

#### *Alveolar macrophages*

Alveolar macrophages are the main phagocytic cell, and hence the primary defence mechanism, of the acinus, although both type II and type I cells have some phagocytic activity. In common with other tissue macrophages, they are derived from bone marrow pro-monocyte stem cells, which enter the circulation as monocytes and reach the lung by diapedesis through the capillary endothelium [95]. Their numbers increase with age in non-smokers [96], and large increases are seen as a consequence of smoking and inhalation of toxic or irritant substances. Their production by bone marrow is regulated by a cytokine, macrophage colony-stimulating factor, which in turn is produced by a wide range of cells. They are capable of penetrating the alveolar epithelium, probably between type I and type II cells mainly, and come to lie in the surfactant layer. They are amoeboid cells and their cytoplasm is rich in electron-dense lysosomal bodies (Fig. 1.16). Frequent phagosomes, containing particulate matter and whorled structures probably representing ingested surfactant, are seen. Alveolar macrophages, being accessible to bronchoalveolar lavage, have been much studied of late. As befits a defence cell analogous in evolutionary terms to soil protozoa, apart from its phagocytic function the alveolar macrophage synthesizes and, when activated, secretes a large number of active products, including lysozyme, proteases, complement components, plasminogen activator, thromboplastin,  $\alpha_2$ -macroglobulin and numerous cytokines, most notably interferon  $\alpha$ , tumour necrosis factor  $\alpha$  and IL-1 and IL-8 [97,98]; it can also release superoxide radical and NO as part of its antibacterial role. Alveolar macrophages play the central role not only in defence of the lung against inhaled organisms and organic and inorganic substances, but also in the inflammatory and immunological reactions that may lead to lung damage by both fibrosis and emphysema [99,100].

Most macrophages, having reached the alveolar surface, either migrate up into the airways, where they are carried to the pharynx in the mucociliary escalator, or die *in situ* and are in turn scavenged by younger phagocytes. There is dispute as to whether macrophages, having engulfed foreign particles, can repenetrate alveolar epithelium and transport the particles into the lymphatics. It is equally likely that the particles themselves penetrate the epithelium by pinocytosis and are phagocytosed by

macrophages resident in the interstitial tissues and thence carried by these cells to lymphatics.

### Surfactant

The inner surface of the alveolar epithelium is separated from the alveolar gas by a thin layer of surface-active material, consisting mainly of dipalmitoyl lecithin and dipalmitoyl phosphatidylethanolamine, combined with apoproteins that are the most hydrophobic proteins known [101,102]. These cationic substances, by means of a positively charged quaternary ammonium ion that separates their two palmitic acid chains, attach themselves to the negatively charged epithelial surface. It was believed

that a liquid layer is present between this surfactant and the epithelial cells and that this is responsible for the inherent instability of alveoli. However, evidence for this liquid layer is scanty while a teleological reason for it is hard to perceive, as it would only increase the instability of alveoli and the force required to keep them inflated. The presence of surfactant reduces the surface tension of the alveolar lining layer to almost zero. This major function of surfactant, decreasing the surface tension of the alveolar wall during expiration and therefore reducing the work of lung inflation, is probably only part of its role; it is likely also that it has an important function as a waterproofing material [103,104]. It has been shown that the presence of surfactant increases considerably the pressure required for

fluid to leak from the alveolar interstitium into alveolar spaces. Moreover, once fluid does escape into alveoli, the hydrophobic surface would tend to break it up into droplets which on the irregular alveolar surface would accumulate in angles and corners. Here the pressure generated by the surface tension of small drops could be sufficient to force fluids back into the interstitium, even against an osmotic gradient [104].

Surfactant is manufactured by the type II alveolar cells, each of which is capable of secreting almost its own weight of the material each day. It is synthesized in the smooth endoplasmic reticulum and appears first as a multivesicular body, which converts into the lamellar body. This changes form to a tubular myelin, a monolayer and a micellar form, and much is then taken back into type II cells for reprocessing [105,106].

As mentioned previously, surfactant synthesis starts after about 26 weeks of fetal life. Thus premature infants run the risk of surfactant deficiency, causing the condition known as respiratory distress syndrome or hyaline membrane disease. At this stage alveoli have not developed and surfactant is necessary to facilitate lung inflation and reduce the work of respiration for the critical first few hours of extrauterine life. Babies with this disease show tachypnoea, chest retraction, expiratory grunting and cyanosis. The chest radiograph may show fine mottling and the lungs feel stiff on ventilation. When death occurs, the lungs show peribronchiolar fibrosis and prominent hyaline membranes in the immature air spaces. Surviving babies may be left with pulmonary fibrosis, a condition known as bronchopulmonary dysplasia, possibly related to the need for treatment with high concentrations of oxygen and assisted ventilation [107]. Mortality from this condition has been reduced dramatically by the use of surfactant replacement therapy using either natural pig or cow surfactant or synthetic phospholipid mixtures [108].

## Blood vessels of the lung

### Bronchial circulation

The bronchial arteries usually arise, either as a pair or as a common trunk, from the descending aorta below the origin of the left subclavian artery [109,110]. There is considerable anatomical variation, the vessels occasionally being branches of the internal mammary artery or intercostal arteries, while small supplementary arteries may arise separately from further down the aorta. Sometimes part of the blood supply of the anterior spinal artery may come from bronchial vessels, an anomaly to beware if bronchial artery embolization for haemoptysis is to be contemplated. The bronchial arteries leave the aorta at an upwards angle, against the direction of blood flow, send branches to oesophagus, mediastinum, lymph nodes and nerves, and on reaching the main bronchi divide into vis-

ceral pleural branches to the mediastinal pleura and true bronchial arteries to the bronchial tree. These latter vessels run a spiral course around the bronchi, one on either side of each bronchus but anastomosing frequently with each other. The vessels form an arterial plexus in the adventitia from which branches pierce the muscle layer to enter the submucosa, where they break up into a capillary plexus. Apart from supplying bronchi, the bronchial arteries also supply nerves, the walls of the pulmonary vessels and intrapulmonary lymph nodes. Arteriolar branches of the visceral pleural vessels pass along interlobular septa, reaching the interstitial tissue of the lung acinus. The true bronchial arteries reach as far down the airways as the terminal bronchiole.

Much of the bronchial arterial blood, having gone through submucosal capillaries, passes into a venous plexus in the adventitia. This low-pressure system can be obstructed by bronchial muscle contraction, probably explaining in part the oedematous mucosa seen in asthma. Veins from this plexus then join the pulmonary venous system. However, bronchial veins have been described from terminal bronchioles to the hilum, also communicating with pulmonary veins or draining directly into the left atrium. The pleurohilar veins, in contrast, drain into the azygos and hemiazygos systems and thus into the right side of the heart. However, there is free communication between pulmonary, bronchial and pleurohilar venous systems within the lung.

### Pulmonary circulation

The pulmonary artery arises from the infundibulum of the right ventricle at the pulmonary valve and runs posteriorly slightly upwards and to the right to divide below the aortic arch into right and left branches (Fig. 1.17). The right runs laterally under the arch and posterior to the ascending aorta and superior vena cava before dividing at the hilum into upper and lower branches, which supply upper lobe and middle and lower lobes respectively. Thereafter branching is very variable, although in general the pattern approximates to that of the bronchial tree. The left main pulmonary artery runs laterally and slightly upwards and posteriorly, anterior to the descending aorta to which it is connected by the ligamentum arteriosum (the remnant of the ductus arteriosus). The left recurrent laryngeal nerve winds round the ligamentum arteriosum, explaining why left hilar disease may cause vocal cord paralysis. The left pulmonary artery divides usually into upper and lower branches, which subdivide in a variable pattern as on the right side. Counting from peripheral small arteries to the main pulmonary trunk, there are 17 orders of branching on both sides [111]. Beyond the first-order vessels lie pulmonary arterioles supplying the acini. These are true end arteries, breaking up into the pulmonary capillaries that form networks around the alveoli.

Fig. 1.17 Normal pulmonary arteriogram.

The pulmonary trunk and large pulmonary arteries exceeding 1 mm in diameter are classified as elastic arteries [112]. The media of these vessels consists predominantly of elastic fibrils (five or more layers) with some smooth muscle fibres, collagen and a mucopolysaccharide ground substance. The elastic tissue pattern in the pulmonary trunk varies with the different phases of development from fetal to adult life, the adult pattern becoming established by the end of the second year. By this time the media is only half to three-quarters as thick as that of the aorta and the elastic tissue is irregular and more sparse, contrasting with the long, parallel, uniform fibrils of the aortic media. Central to a thick internal elastic lamina is a fibrous intima and the vascular endothelium.

The elastic arteries give rise to muscular arteries with a diameter less than 1 mm. These vessels have a thin media of circular smooth muscle between internal and external elastic laminae, the latter having first appeared in the smaller elastic arteries. The thin fibrous intima gradually disappears, leaving the internal elastic lamina bounded by endothelial cells. The muscular arteries are closely associated with bronchioles, branching with them. They in turn give rise to pulmonary arterioles, defined as vessels below 0.1 mm in diameter. These essentially consist of an endothelial lining, a single elastic lamina and very thin or absent adventitia. They are indistinguishable from pul-

monary venules except when they can be traced to their origin from a muscular artery.

Pulmonary capillaries consist of endothelial cells stretched over basement membrane. These capillaries spread as a network around the alveoli and collect together to form venules that start near bronchioles but then run into the connective tissue septa between secondary veins which run in the interlobular septa. Pulmonary veins have a thick fibrous adventitia, a media of irregularly disposed collagen and muscle fibres, an internal elastic lamina and endothelium. Usually the veins join into four main vessels, two from each lung, before entering the left atrium.

The pulmonary endothelial cell appears almost featureless on light microscopy, with a flattened cytoplasm and bulging nucleus. Silver stains demonstrate a pavement pattern that differs in shape in different vessels, while electron microscopy of rat pulmonary endothelium has shown the cytoplasm to have both projections into the lumen and vesicular structures called *caveolae intracellulares* [93]; these may communicate with the vessel lumen through small openings. Endothelial cells are the site of enzymes concerned with the conversion of angiotensin I into angiotensin II, and are the main cells concerned with the synthesis of NO, a smooth muscle relaxing factor [94,113]. The pulmonary circulation is known to be

responsible for degradation of a number of circulating hormones and drugs and it is likely that many of these functions are also subserved by the endothelial cell, either on its surface or by pinocytosis.

Endothelial cells account for almost 40% of the cell population of the lung and have a rapid rate of turnover. In the larger vessels they are connected by tight junctions [93], while in capillaries small gaps between cells may occur that allow passage of fluid into the interstitial space. Such fluid is normally unable to pass into alveoli because of the tight junctions between epithelial cells and therefore drains to the lymphatics around the pulmonary venules in the interlobular septa. The endothelial cell is vulnerable to injury caused by, for example, radiation, drugs such as bleomycin, or high concentrations of oxygen. The damage, probably mediated by free oxygen radicals, results in vacuolation, swelling and rupture of endothelial cells, platelet deposition on basement membrane, interstitial oedema and ultimately alveolar epithelial damage and alveolar oedema [89]. Thrombotic occlusion of the capillary may occur. At an early stage these changes are reversible, the endothelial cell having a remarkable regenerative capacity.

## Lymphatics of the lung

Two lymphatic networks drain the lung. The superficial system arises in the pleura, forming an arrangement of irregular polyhedra marking the edges of the secondary lung lobules [109]. The deep system arises in connective tissue between the acini and around bronchi and vessels [114]. The two networks communicate in the pleura and at the hila. The vessels themselves are thin-walled, being lined with endothelium and consisting of collagen, elastic fibres and some longitudinal muscle bundles [109]. Their wall varies in thickness and often consists almost entirely of the endothelium. They contain numerous valves, which have a conical structure, approximately 1–2mm apart. These valves are placed so as to direct flow for variable distances along the pleura, but ultimately most pleural vessels enter the parenchyma and pass towards the hila through interlobular and peribronchovascular channels. Lymph drains finally into the systemic venous system at the junctions of the subclavian and internal jugular veins via the thoracic duct on the left and the right lymphatic duct on the right.

Aggregations of lymphoid tissue are found in the angles of bronchial branches from the periphery inwards. The most distal of these aggregations surround the division of the last respiratory bronchiole into alveolar ducts. True lymph nodes (the bronchopulmonary nodes) are not found until the first division of the lobar bronchi [115]. The hilar nodes, around the main lobar bronchi, form part of a large group clustered about the lung root. The nodes lying lateral and inferior to the tracheal bifurcation are the

upper and lower tracheobronchial groups. The lower group lies in the carina and unites the tracheobronchial groups of the two sides. The upper tracheobronchial group is usually larger on the right. On the left side, one or more para-aortic nodes are separated from the upper tracheobronchial group by the aorta and pulmonary artery. These are closely associated with the ligamentum arteriosum, recurrent laryngeal nerve and vagal fibres to the pulmonary plexus. On either side of the trachea, paratracheal nodes are also close to the recurrent laryngeal nerve and involvement of these nodes by bronchial carcinoma commonly results in vocal cord paresis. Efferent vessels from the paratracheal nodes pass to the lower deep cervical nodes. Other intrathoracic groups are the sternal nodes, on the inner surface of the anterior chest wall along the distribution of the internal mammary arteries, the internal intercostal nodes near the heads of the ribs, and the anterior and posterior mediastinal nodes.

The pattern of pulmonary lymph drainage is complex and variable. Extrapulmonary drainage may occur through interconnecting mediastinal, paratracheal and subdiaphragmatic channels. The classical pathways have been described as follows [115].

- 1 Upper two-thirds right upper lobe: right tracheobronchial nodes.
- 2 Lower third right upper lobe: dorsolateral hilar nodes.
- 3 Right middle lobe: hilar nodes around middle lobe bronchus.
- 4 Dorsolateral parts of right lower lobe: dorsolateral hilar nodes.
- 5 Ventromedial parts of right lower lobe: ventromedial hilar and carinal nodes.
- 6 Apex left upper lobe: para-aortic nodes.
- 7 Rest of left upper lobe: anterior and posterior hilar and carinal nodes.
- 8 Left lower lobe: similar to right lower lobe.

The lower lobes also drain to nodes in the posterior mediastinum and, through the diaphragm, to retroperitoneal nodes (Fig. 1.18). The main primary and secondary drainage pathways of the lungs are shown in Figs 1.19 and 1.20 [116].

In normal lung, the lymphatics are barely visible microscopically. However, they become very distended and easily visible in pulmonary oedema and their presence may become apparent on chest radiographs. Distended anastomotic channels between perivenous- and peribroncho-arterial vessels are seen as Kerley A lines, while thickening of the interlobular septa around dilated subpleural interlobular lymphatics is seen as Kerley B lines. Such appearances occur typically in pulmonary oedema, lymphatic spread of carcinoma and some pneumoconioses [117].

Homeostasis in relation to the volume of pulmonary interstitial fluid depends on lymphatic drainage, as implied above. Lymphatic vessels, containing valves and

**Fig. 1.18** Pulmonary lymph glands: note connections with neck and abdominal glands (From von Hayek [115].)

**Fig. 1.19** Schematic representation of the primary (heavy line and shaded circles) and secondary (thin lines and open circles) lymphatic drainage pathways of the right lung following injection of the lobar lymph node complex shown. (From Dyon [116].)

smooth muscle, can probably actively increase lymph transport when the amount of interstitial fluid is increased [118,119]. Pulmonary oedema occurs when this capacity is overwhelmed. The dilatation of lymph vessels seen in pulmonary oedema is perhaps surprising in view of their delicate walls and the increased interstitial pressure that

**Fig. 1.20** Schematic representation of the primary (heavy line and shaded circles) and secondary (thin lines and open circles) lymphatic drainage pathways of the left lung following injection of the lobar lymph node complex shown. (From Dyon [116].)

surrounds them. However, they contain fluid themselves under the same pressure, and this, together with their valvular mechanism and fine fibrillar connections to surrounding tissue, keeps them patent and preserves their ability to drain fluid [120,121].

## Innervation of the lung

Autonomic nerves from the vagi and second to fourth thoracic sympathetic ganglia form the pulmonary plexus from which arise branches to supply the bronchi and vessels of the lung [122–125]. The trachea receives branches directly from the right vagus and recurrent laryngeal nerve. In cartilage-containing airways, a plexus is present both outside and within the plates. Non-myelinated fibres innervate the smooth muscle of the bronchi and bronchioles and the bronchial glands. Similar fibres pass along the pulmonary and bronchial arteries, while the pulmonary veins receive their nerves from those supplying the left atrium [109].

Parasympathetic nerves from the vagus carry afferent messages from stretch receptors within the lung, from juxtacapillary J receptors and from bronchial irritant receptors [125]. Efferent parasympathetic fibres mediate bronchoconstriction [126], bronchial gland secretion and probably pulmonary vasodilatation. Sympathetic innervation of vascular smooth muscle has been demonstrated

in most animals studied, although its role in pulmonary vasoconstriction in humans is unknown. Sympathetic innervation of bronchial smooth muscle is probably absent or of no functional significance [122].

There is evidence of a third component of the autonomic nervous system in the lung, as in other tissues such as the gut and the cardiovascular system [122,127]; this is called the peptidergic or non-adrenergic non-cholinergic system. These nerves travel with other autonomic nerves but are distinguishable histochemically and in experiments on isolated smooth muscle. The mediators are peptides, of which four seem particularly important. Vasoactive intestinal peptide is a 28-amino-acid peptide that relaxes bronchial and vascular smooth muscle and has an anti-inflammatory effect [122,128]. It has been found in human bronchial muscle, mucous glands, pulmonary and bronchial vessels, and in neutrophils, eosinophils and monocytes. It probably acts within the cell by activation of adenylate cyclase, like sympathetic stimulation, increasing levels of cyclic AMP [129]. The opposite effect, resulting in smooth muscle constriction, vasodilatation, increased vascular permeability and fluid transudation, and increased mucus secretion, is mediated via sensory nerves that respond to irritant stimuli by release of substance P, neurokinin A and calcitonin gene-related peptide [130–132].

Understanding of the interrelationships of the three components of the autonomic control of airways and lung vasculature is far from complete. It seems likely that neural control is largely exerted by parasympathetic and peptidergic systems, while humoral control is mediated via the adrenal medulla. New research in this area should have important practical applications in the understanding of asthma and pulmonary hypertension, and has major implications for new methods of therapy.

## Pleura

The pleura is a serous layer of mesodermal origin. It consists of a single layer of mesothelial cells, without a basement membrane. A layer of compressed connective tissue, which may be up to 100  $\mu\text{m}$  thick, separates it from the adipose tissue of the chest wall and from alveoli [133]. The visceral pleura, which covers the lung and is indented into the fissures, is continuous at the hilum with the parietal pleura that lines the hemithorax. A thin double fold of pleura below the hilum and extending almost to the diaphragm is called the pulmonary ligament.

The parietal and visceral layers have traditionally been thought to be separated normally by a small quantity of

lubricating fluid. This fluid is probably derived largely from parietal pleural capillaries and reabsorbed by lymphatics, predominantly in costal and mediastinal parietal pleura [134]. This drainage pathway may be blocked when tumour cells are introduced and deposits form in the draining lymph nodes, leading to pleural effusion. The pleural space only becomes apparent when such transudation or exudation of fluid between the two layers exceeds the drainage capacity of pleural lymphatics (see Chapter 43). However, a convincing case has been made for surfactant rather than fluid as the principal lubricating system of the pleural surfaces [135]. The cells of the pleural membrane have ovoid nuclei and thin cytoplasm. The subjacent connective tissue varies in different parts of the pleura, being predominantly collagenous over the pericardium and elastic over the diaphragm and ribs. Beneath the visceral pleura there is a thin layer of elastic and collagen fibres, a strong fibrous layer and a vascular connective tissue layer contiguous with the interlobular septa. Outside the parietal pleura is a band of compressed connective tissue, a fatty layer and another band of predominantly elastic tissue that separates it from rib perichondrium, intercostal muscle and diaphragm.

The visceral pleura is supplied mainly by branches of the bronchial artery that divide into a network of very dilated capillaries [109,115]. The costal parts of the parietal pleura are supplied by intercostal arteries, while the diaphragmatic and mediastinal parts are supplied by the pericardiophrenic branch of the internal mammary artery. The lymphatics of the visceral pleura drain subpleurally into interlobular vessels and thence to hilar nodes as described above. The lymphatics from the costal parietal pleura drain into internal mammary and intercostal nodes, providing a useful site for biopsy in the diagnosis of pleural disease [136]. Vessels over the diaphragmatic visceral pleura drain to internal mammary and anterior and posterior mediastinal nodes, while those from mediastinal pleura accompany the pericardiophrenic artery draining into the posterior mediastinal nodes.

The visceral pleura is supplied by autonomic nerves only. However, sensory nerves are present in the parietal pleura, from spinal nerves over the ribs and from the phrenic nerve over the central part of the diaphragm. The peripheral diaphragmatic pleura receives sensory fibres from intercostal nerves. Pleural pain therefore represents stimulation of the parietal receptors, and the presence of a phrenic supply to the central diaphragmatic pleura explains the referral of pain from diaphragmatic pleurisy to the shoulder tip. Other pleural pain is referred to the chest wall.

# FUNCTIONS OF THE LUNG

A. GORDON LEITCH

The principal functions of the lungs are to add oxygen ( $O_2$ ) to, and remove carbon dioxide ( $CO_2$ ) from, pulmonary arterial blood. Achievement of these functions is reflected by the maintenance of the partial pressures of these gases in systemic arterial blood within the normal ranges, i.e.  $P_{aO_2}$  10.5–13.5 kPa (80–100 mmHg) and  $P_{aCO_2}$  4.8–6.0 kPa (36–45 mmHg). Normality of arterial blood gas tensions is maintained by the efficient transfer of gas from the alveoli through the alveolar membrane to the mixed venous blood that passes through the pulmonary capillaries. There are thus three components contributing to the process of gas exchange.

1 *Ventilation*: movement of gas in and out of the lungs is provided by their bellows' action and must be adequate in volume and appropriate in distribution to perfused alveoli.

2 *Perfusion*: the output of mixed venous blood from the right ventricle must also be adequate in volume and appropriate in distribution to capillaries perfusing ventilated alveoli.

3 *Diffusion*: where gas and blood are brought into contact across the alveolar–capillary membrane, there should be no significant impediment to the diffusion of gases between them.

Ventilation and perfusion are remarkably integrated in health by a series of complex mechanisms, and the whole process of pulmonary gas exchange is achieved with the minimum expenditure of energy by the respiratory and cardiovascular systems.

## Ventilation

Pulmonary ventilation, or the mass movement of gas up and down the bronchial tree, depends on the rhythmic inflation and deflation of the lungs. Contraction of the intercostal muscles and of the diaphragm causes an upward and outward movement of the ribs and flattening of the diaphragm during quiet inspiration. During vigorous breathing the accessory muscles of respiration (the sternomastoids, the scaleni, the pectorals and the latis-

simus dorsi) also come into play. Expiration is essentially passive but may be assisted during vigorous breathing by contraction of the abdominal muscles. Contraction of the inspiratory muscles lowers the intrathoracic and alveolar pressures so that air flows from atmospheric pressure at the mouth or nose to the subatmospheric pressures prevailing in the alveoli. During expiration the elastic recoil of the chest wall and lungs raises intrathoracic and alveolar pressures so that gas flow is reversed. The rhythmicity, rate and depth of respiration are controlled by the respiratory centre with its numerous inputs to ensure that appropriate alveolar ventilation is achieved with minimal energy cost [1].

## Minute ventilation

The minute ventilation, the volume of gas moved into ( $\dot{V}_I$ ) or out of ( $\dot{V}_E$ ) the lungs in 1 min, can be measured by a variety of techniques [2]; in normal resting subjects at sea level it is about 6–10 L/min (measured at body temperature and pressure when saturated with water, BTPS) and is related to body size. Trained athletes can achieve a minute ventilation of up to 200 L/min [3] during exercise but untrained individuals are unlikely to achieve values higher than 100 L/min. The normal frequency of breathing in adults at rest is 8–18 breaths/min and the volume of gas moved in and out of the lungs with each breath, the tidal volume ( $V_T$ ), is therefore about 500 mL.

## Anatomical dead space

Not all of the tidal volume contributes to gas exchange since at the end of inspiration some of it fills the conducting airways (where no gas exchange occurs) and the rest has mixed with the gas occupying the alveoli where gas exchange occurs (Fig. 2.1). The volume of the conducting airways where gas exchange does not occur is called the anatomical dead space and is about 150 mL in an average person. The anatomical dead space is decreased 60% by tracheostomy [4].

Fig. 2.1 Anatomical dead space. A tube (the conducting airways) leads into a balloon (the alveoli). At the end of expiration (a) the tube is filled with 150 mL of alveolar gas. At the end of inspiration (b), with a tidal volume of 450 mL, the alveoli receive the 150 mL of alveolar gas plus 300 mL of air, and 150 mL of air then occupies the conducting airways. Each block then represents 150 mL. (Modified from Comroe *et al.* [5].)

Anatomical dead space is measured by continuous analysis of the nitrogen ( $N_2$ ) concentration in the expired gas and simultaneous measurement of expired volume.  $N_2$  is used because it does not take part in gas exchange. By means of an  $N_2$  meter a single expiration is monitored following a deep breath of  $O_2$  (Fig. 2.2). The first part of the record at the beginning of expiration represents pure dead space gas in which no  $N_2$  is present. This is followed by a short phase of rapidly rising  $N_2$  concentration, where mixed dead space gas and alveolar gas is being expired, and finally by the pure alveolar sample, which reflects the degree of dilution of alveolar  $N_2$  by the  $O_2$ . If no mixing occurred in the airways the rise in  $N_2$  concentration would occur abruptly as a square front and the anatomical dead space would be the amount expired at this point. The theoretical situation of a square front can be determined by the method of Fowler, which divides the rising phase of the curve into two equal parts; this gives the anatomical dead space [5].

The simplified situation illustrated in Fig. 2.1 does not occur in practice for the tidal volume moves with a cone rather than a square front, thus partly explaining the occurrence of gas exchange when the lungs are ventilated at high frequencies and with tidal volumes less than the anatomical dead space (high-frequency ventilation) [6].

Fig. 2.2 Estimation of dead space by single-breath analysis; see text for explanation. (Modified from Comroe *et al.* [5].)

### Physiological dead space and alveolar ventilation

The physiological dead space ( $V_D$ ) is the volume of gas in the lungs that takes no part in gas exchange. It includes the anatomical dead space and the alveolar dead space, i.e. the volume of gas in alveoli that behaves as if it did not participate in gas exchange. The physiological dead space can be calculated using the Bohr equation [5], where  $P_{ECO_2}$  is the partial pressure of  $CO_2$  in expired gas:

$$V_D = \frac{(P_{ACO_2} - P_{ECO_2}) \times V_T}{P_{ACO_2}} \quad [2.1]$$

assuming that  $P_{ACO_2} = P_{ACO_2}$ . This method simply requires analysis of expired air and of a sample of arterial blood. The ratio of dead space to tidal volume in a physically normal human is about 30%; the dead space is increased in relation to anatomical dead space when there are significant volumes of lung with ventilation disproportionately high in relation to perfusion.

When the physiological dead space is known, the alveolar ventilation ( $\dot{V}_A$ ), i.e. the volume ventilating the gas-exchanging part of the lung, can be calculated. For a given minute ventilation, alveolar ventilation may vary widely depending on the combinations of tidal volume and frequency of breathing employed (Fig. 2.3). Alveolar ventilation may also be derived from knowledge of the concentration of  $CO_2$  in alveolar gas ( $F_{ACO_2}$ ) and the  $CO_2$  output ( $\dot{V}_{CO_2}$ ). Since all the  $CO_2$  in expired gas comes from the alveoli, it follows that  $\dot{V}_{CO_2} = \dot{V}_A \times F_{ACO_2}$ .

This equation can be rewritten in terms of mean alveolar or arterial  $P_{CO_2}$  with the inclusion of a correction factor:

$$\dot{V}_A (\text{BTPS}) = \frac{\dot{V}_{CO_2} (\text{STPD}) \times 0.863}{P_{ACO_2}} \quad [2.2]$$

There is a hyperbolic relationship between alveolar ventilation and  $P_{CO_2}$ , if  $\dot{V}_{CO_2}$  is constant. For example, if  $\dot{V}_A$  doubles,  $P_{ACO_2}$  halves. A decrease in alveolar ventilation causes  $P_{CO_2}$  to rise (as in respiratory failure, see Chapter

**Fig. 2.3** Effect of increasing respiratory frequency at constant minute ventilation (8 L/min) on alveolar ventilation ( $\dot{V}_A$ ). The dead space ( $V_D$ ) is constant and as respiratory frequency increases (D–F) tidal volume falls and a greater proportion of each tidal volume occupies dead space. The resultant changes in alveolar ventilation are shown in (A–C).

24) and an increase in alveolar ventilation causes  $P_{CO_2}$  to fall.

### Alveolar air equation

For practical purposes there are four gases in the alveoli ( $O_2$ ,  $CO_2$ ,  $N_2$ ,  $H_2O$ ) and three in inspired air ( $O_2$ ,  $N_2$ ,  $H_2O$ ). Since neither  $N_2$  nor  $H_2O$  participates in net exchange in the lungs it follows that

$$P_{IO_2} = P_{AO_2} + P_{ACO_2} \text{ or} \quad [2.3]$$

$$P_{AO_2} = P_{IO_2} - P_{ACO_2}$$

This equation is correct if the ratio of  $CO_2$  output/ $O_2$  uptake (respiratory exchange ratio,  $R$ ) equals 1. If  $R$  does not equal 1, then the assumption of constancy of alveolar  $P_{N_2}$  is not justified, for  $O_2$  uptake will exceed  $CO_2$  output with resultant concentration of  $N_2$  molecules in the alveoli and increase in  $P_{O_2}$ . Correction for the known value of  $R$  is then required:

$$P_{AO_2} = P_{IO_2} - \frac{P_{ACO_2}}{R} \quad [2.4]$$

Since  $P_{ACO_2} = P_{ACO_2}$  for all practical purposes and  $P_{IO_2}$  is known,  $P_{AO_2}$  can be determined from measurement of arterial blood gas tensions if a value for  $R$  is either assumed or measured.

Since  $P_{AO_2}$  is usually measured at the same time as  $P_{ACO_2}$ , the alveolar–arterial  $P_{O_2}$  difference can be calculated. This is usually less than 2 kPa (15 mmHg) in normal subjects but is increased in disease and serves as a measure of ventilation–perfusion inequality. Determination of the alveolar–arterial  $P_{O_2}$  difference in this way for all blood gas samples is a useful exercise that often serves as a check on the reliability of the sample.

**Fig. 2.4** Approximate partial pressures at various points in the respiratory system (1 kPa = 7.5 mmHg).

### Partial pressures of oxygen and carbon dioxide in the respiratory system

At an atmospheric pressure of 100 kPa (750 mmHg) dry air contains 20.9%  $O_2$ , 0.03%  $CO_2$  and 79.03%  $N_2$  (with minor contributions from other gases), the approximate partial pressures for these gases being 21 kPa (157 mmHg) for  $O_2$ , 0.03 kPa (0.2 mmHg) for  $CO_2$  and 79 kPa (593 mmHg) for  $N_2$ . These partial pressures fall slightly in the airways due to humidification (Fig. 2.4), and  $P_{O_2}$  falls further in the alveoli where  $O_2$  diffuses to pulmonary capillary blood. Since  $O_2$  transport is not perfect in the lungs,  $P_{AO_2}$  is slightly less than  $P_{AO_2}$ ; the  $P_{O_2}$  of blood falls further in the tissues where  $O_2$  is utilized, this change being reflected in the  $P_{O_2}$  of mixed venous blood (Fig. 2.4).

The respiratory control system seems to be set to maintain  $P_{ACO_2}$  at about 5.3 kPa (40 mmHg).  $P_{CO_2}$  is higher in the tissues as a result of metabolic production of  $CO_2$ , which is transported to capillary blood and leads to an increase in the  $P_{CO_2}$  of mixed venous blood. For practical purposes mean alveolar and arterial  $P_{CO_2}$  are identical.

Fig. 2.5 Lung volumes: a water-filled spirometer can be used to provide a trace of lung volumes (see text). The functional residual capacity and residual volume need to be calculated by other methods (see Figs 2.6 & 2.7). (From West [7].)

Finally, the  $P_{O_2}$  and  $P_{CO_2}$  of expired gas reflect expiration of a mixture of inspired air from the dead space and alveolar gas.

### Lung volumes

The static lung volumes can be measured by a simple spirometer (Fig. 2.5). Quiet breathing records the tidal volume ( $V_T$ ), and a maximal inspiration followed by a maximal expiration defines the vital capacity (VC). The inspiratory reserve volume (IRV) and expiratory reserve volume (ERV) can be calculated from such a tracing.

The functional residual capacity (FRC), the volume of gas remaining in the lung at the end of a quiet expiration, and the residual volume (RV), the volume of gas remaining in the lung after a maximal expiration, can be determined by one of two methods. With the helium (He) dilution method [8] the subject is connected, at the end of a quiet expiration, to a closed spirometer containing a known concentration and volume of He, a gas that is almost insoluble in blood. After a period of equilibration, the concentration of He in the lungs and the spirometer stabilizes at a new level and the FRC can be calculated as shown in Fig. 2.6. Alternatively, the FRC can be measured with the subject sitting in a body plethysmograph and attempting to breathe against a closed mouthpiece while the pressures in the mouthpiece and the plethysmograph are recorded (Fig. 2.7). As the subject breathes in, the gas in the lung expands, which increases lung volume and simultaneously decreases plethysmograph volume with a resultant rise in plethysmograph pressure. The FRC is calculated using Boyle's law:

$$P_1 V = P_2 (V + \Delta V) \quad [2.5]$$

where  $P_1$  is resting mouth pressure,  $P_2$  is pressure on inspiration,  $V$  is FRC and  $\Delta V$  is the rise in lung volume on inspiration.  $\Delta V$  can be determined from the increase in plethysmograph pressure based on earlier volume calibra-

Fig. 2.6 Measurement of functional residual capacity (FRC). Before equilibration a known volume of a known concentration of helium is in the spirometer. After equilibration, when the helium concentration is constant at a new level, the FRC ( $V_2$ ) can be calculated from the following equation:  $C_1 \times V_1 = C_2 \times (V_1 + V_2)$ . (Modified from West [7].)

Fig. 2.7 Measurement of functional residual capacity (FRC) using a body plethysmograph. The subject makes an inspiratory effort against a closed airway with a resultant fall in airway pressure, rise in lung volume and rise in the box pressure. FRC can be calculated using Boyle's law (see text). (Modified from West [7].)

tions of the plethysmograph,  $P_1$  and  $P_2$  are both measured and thus  $V$  or FRC can be calculated.

The plethysmographic method measures the total volume of gas being compressed in the lungs and in normal subjects this agrees well with values of FRC determined by He dilution. In some patients, e.g. with lung cysts or emphysema, lung gas may equilibrate poorly with the He in the dilution method ('trapped gas') and then FRC determined in the plethysmograph exceeds that using He dilution. However, if the He equilibrium phase is prolonged, agreement between the two methods improves [9].

When FRC has been determined, it is easy to compute RV and total lung capacity (TLC) (Fig. 2.5). An alternative method of determining TLC is from measurements derived from postero-anterior and lateral chest radiographs [10–12].

## Perfusion: the pulmonary circulation

At rest the right ventricle pumps blood through the pulmonary circulation at a rate of about 5L/min. The mean pulmonary artery pressure is only about 2kPa (15mmHg), and since blood flow = driving pressure / resistance the resistance in the pulmonary circulation is only about one-tenth that of the systemic circulation. The pulmonary circulation has a remarkable reserve capacity, which is due to the great distensibility of the pulmonary vasculature and also to recruitment of capacitance vessels not in use.

## Control of pulmonary circulation

There is no known effective nervous control over pulmonary vascular resistance [13]. However, an efficient regulatory mechanism exists in the normal lung based on the partial pressure of  $O_2$  and  $CO_2$  in the blood. Hypoxia increases pulmonary vascular resistance [14,15], possibly by a direct effect of  $PAO_2$  on pulmonary vessels [16], an observation of major importance in understanding the pathophysiology of respiratory failure. Similarly, a fall in local  $PACO_2$  after obstruction of a pulmonary artery results in a 25% reduction in local ventilation [17], suggesting the existence of a local homeostatic mechanism, based on the prevailing partial pressures of  $O_2$  and  $CO_2$ , that operates to match ventilation and perfusion.

## Variation in pulmonary circulation

The pulmonary circulation is increased in exercise, thyrotoxicosis, fever, anaemia and left-to-right shunts, and decreased in cardiac failure and right-to-left shunts. The fact that the pulmonary circulation may double without a rise in pulmonary vascular pressure only holds true if the resistance is not increased [18] (Fig. 2.8). Pulmonary vascular resistance may be increased when there is a reduction in the number and calibre of pulmonary vessels, such as may occur in extensive lung resection, multiple embolism, pulmonary vasculitis, primary pulmonary hypertension and, most commonly, the pulmonary attrition associated with chronic bronchitis and emphysema.

## Pulmonary oedema

The pressures operating on a pulmonary capillary are shown in Fig. 2.9. Because pulmonary capillary pressure is low and less than colloid osmotic pressure, fluid tends to be drawn into the capillaries. When pressure rises in the capillaries, as seen in mitral stenosis and left ventricular failure, it may exceed colloid osmotic pressure and lead to transudation of fluid across the capillary membrane into the interstitium and the alveoli, resulting in pulmonary

**Fig. 2.8** Mean pulmonary artery pressure responses to increasing cardiac output. The normal pulmonary vascular bed can tolerate an increase in cardiac output to 250% before pulmonary artery pressure rises. In patients with a restricted pulmonary vascular bed, pulmonary artery pressure rises sharply with even a small increase in cardiac output. (From Robin & Gaudio [18].)

**Fig. 2.9** Forces acting across an alveolar-capillary membrane.

oedema. Not all cases of mitral stenosis with a raised pulmonary artery pressure have pulmonary oedema and this may be due to a compensatory rise in interstitial fluid pressure that prevents transudation from the pulmonary capillaries [19]. Pulmonary oedema may also occur when the permeability of the alveolar capillary membrane is increased, allowing the passage of protein-rich material

into the interstitium and alveolar spaces, as occurs in adult respiratory distress syndrome [20–23].

### Measurement of pulmonary blood flow

Pulmonary blood flow [24] can be measured by the direct Fick method, using the following equation:

$$\text{Cardiac output or blood flow (L/min)} = \frac{\text{O}_2 \text{ uptake (mL/min)}}{\text{arterial-venous O}_2 \text{ difference (mL/L)}} \quad [2.6]$$

Other methods include the indirect Fick method using nitrous oxide [25] and the dye-dilution method [26].

### Distribution of ventilation and perfusion and $\dot{V}_A/\dot{Q}$ relationships

#### Ventilation-perfusion ratios

The commonest cause of failure to oxygenate mixed venous blood adequately is an imbalance between alveolar ventilation ( $\dot{V}_A$ ) and pulmonary capillary blood flow ( $\dot{Q}$ ) [27,28]. Even in normal lungs, ventilation and perfusion are not distributed evenly as a consequence of gravitational effects and the pleural pressure gradient [29,30]. After inhalation of  $^{133}\text{Xe}$  gas, measurement of radioactivity over different regions of the chest demonstrates that, during normal breathing in the erect position, ventilation increases from the apex to the base of the lung [31] (Fig. 2.10). Similarly if  $^{133}\text{Xe}$  is injected into the bloodstream it passes into alveolar gas because of its low solubility in blood and its concentration in the alveoli, which reflects local pulmonary blood flow, can also be measured. Again, blood flow increases from apex to base of the lung (Fig. 2.10), with remarkably little blood flow reaching the apex of the lung [31]. The regional differences in circulation are much more marked than the regional differences in ventilation.

Studies with an isolated lung preparation have resulted in a scheme that satisfactorily explains the distribution of blood flow in the normal lung in the upright position [32] (Fig. 2.11). The lung is divided, from the top down, into three zones by the relative magnitudes of the pulmonary arterial, venous and alveolar pressures. In zone I, which extends to 4 cm below the apex, arterial pressure is less than alveolar and there is no flow, presumably because collapsible vessels are directly exposed to alveolar pressure. In zone II, the arterial pressure exceeds alveolar pressure, which in turn exceeds venous pressure. Here the vessels behave as Starling resistors (i.e. collapsible tubes surrounded by a variable pressure chamber) and flow is determined by the difference between arterial pressure (which is increasing down the lung) and alveolar pressure (which is constant). In the bottom zone, zone III, venous pressure exceeds alveolar and flow is determined by the

Fig. 2.10 Simplified graph based on  $^{133}\text{Xe}$  studies of ventilation and perfusion showing the relative distribution of ventilation, perfusion and ventilation-perfusion ratios from the apex to the base of the upright lung.

usual arterial-venous pressure difference. Flow increases down this zone because the transmural pressure of the vessels increases, increasing the calibre of the vessels. A fourth zone, at the extreme lung bases, has been shown to have reduced blood flow for reasons not fully understood but possibly due to increased interstitial pressure around small vessels [33,34].

From such studies it is obvious that the ratio of ventilation to perfusion ( $\dot{V}_A/\dot{Q}$  ratio) changes from top to bottom of the lung even in health. The apex is relatively well ventilated with respect to perfusion and has a high  $\dot{V}_A/\dot{Q}$  ratio, whereas the opposite applies to the base of the lung which has a low  $\dot{V}_A/\dot{Q}$  ratio. This well-ordered gradient of  $\dot{V}_A/\dot{Q}$  ratios in the healthy lung maintains normal gas tensions in arterial blood. However, in lung disease disturbance of the normal balance of  $\dot{V}_A/\dot{Q}$  ratios in the lung results in hypoxaemia.

The consequences of abnormal  $\dot{V}_A/\dot{Q}$  ratios can be appreciated by considering the ranges of  $\dot{V}_A/\dot{Q}$  ratios that are possible. Figure 2.12(a) shows a normal alveolus with average  $\text{O}_2$  and  $\text{CO}_2$  tensions. Figure 2.12(b) shows an alveolus receiving no ventilation that has a  $\dot{V}_A/\dot{Q}$  ratio of zero and gas tensions approximating those of mixed venous blood. Figure 2.12(c) shows an alveolus with no perfusion, a  $\dot{V}_A/\dot{Q}$  ratio of infinity and gas tensions similar to those of air. It follows that alveoli in the apex of the normal lung with a high  $\dot{V}_A/\dot{Q}$  ratio have a higher  $P_{\text{O}_2}$  and a lower  $P_{\text{CO}_2}$  than alveoli in the base of the lung where the  $\dot{V}_A/\dot{Q}$  ratio is low (see Fig. 2.10). Since most of the blood

**Fig. 2.11** Topographical distribution of blood flow in the lung; see text for explanation. (From West *et al.* [32] with permission.)

**Fig. 2.12** Effect of changes in the  $\dot{V}_A/\dot{Q}$  ratio on alveolar  $P_{O_2}$  and  $P_{CO_2}$  (see text). 1 kPa = 7.5 mmHg. (Modified from West [35].)

passes through the base of the lung whereas ventilation is more uniform, it follows that there will be a difference between mean alveolar and arterial  $P_{O_2}$ :  $P_{aO_2}$ , determined more by the tensions prevailing in the gas-exchanging units in the bottom of the lung, is 0.6 kPa (4.5 mmHg) lower on average than  $P_{AO_2}$ .

When the number of extreme  $\dot{V}_A/\dot{Q}$  values increases, as in most pulmonary diseases,  $P_{aO_2}$  may fall further. Units with a low  $\dot{V}_A/\dot{Q}$  ratio add less  $O_2$  to the pulmonary capillary blood than normal units; units with a high  $\dot{V}_A/\dot{Q}$  ratio add little more  $O_2$  to blood than normal units, a finding explained by the non-linear shape of the  $O_2$  dissociation curve (see Fig. 2.15). A fall in  $P_{aO_2}$  from normal produces a greater fall in  $O_2$  content than a rise from normal produces an increase. The  $O_2$  content of mixed blood from alveoli with such a range of  $\dot{V}_A/\dot{Q}$  abnormalities tends to reflect the contribution from low  $\dot{V}_A/\dot{Q}$  alveoli, and arterial  $O_2$  content and  $P_{aO_2}$  falls as a result.  $P_{aCO_2}$  should also rise in

such a situation and for similar reasons. However, the central chemoreceptors, which sense  $P_{aCO_2}$ , respond to an increase in  $P_{aCO_2}$  by increasing alveolar ventilation and restoring it to normal.

That  $P_{aCO_2}$  can be restored to normal by an increase in alveolar ventilation while  $P_{aO_2}$  remains low again reflects differences in the  $O_2$  and  $CO_2$  dissociation curves (see Figs 2.15 & 2.19). The latter is linear and therefore a rise in alveolar ventilation increases the  $CO_2$  output of lung units with high as well as low  $\dot{V}_A/\dot{Q}$  ratios. However,  $O_2$  uptake only increases significantly in those units with a low  $\dot{V}_A/\dot{Q}$  ratio, little further increase being possible in those with high  $\dot{V}_A/\dot{Q}$  ratios.

The multiple inert gas technique [36,37] has now made it possible to characterize ventilation-perfusion ratios in more detail in health and disease. A solution containing six inert gases ( $SF_6$ , ethane, cyclopropane, halothane, ether and acetone) is slowly infused into a peripheral vein and, after a steady state of elimination by the lungs has been achieved, the concentrations are measured in the arterial blood and expired gas by gas chromatography. As the gases have different solubilities in blood, they partition themselves between blood and gas according to the  $\dot{V}_A/\dot{Q}$  ratio of the lung unit. It is thus possible to derive a virtually continuous distribution of  $\dot{V}_A/\dot{Q}$  ratios that is consistent with the measured pattern of elimination. Figure 2.13(a) shows such a distribution in a healthy subject, where most of the ventilation and perfusion occurred in lung units with a  $\dot{V}_A/\dot{Q}$  ratio of about 1. In contrast, Fig. 2.13(b) shows the findings in a subject with chronic bronchitis and emphysema in whom large amounts of perfusion occurred in units with a low  $\dot{V}_A/\dot{Q}$  ratio, constituting a *physiological shunt* with resulting hypoxaemia [39]. Similarly, in patients with pulmonary

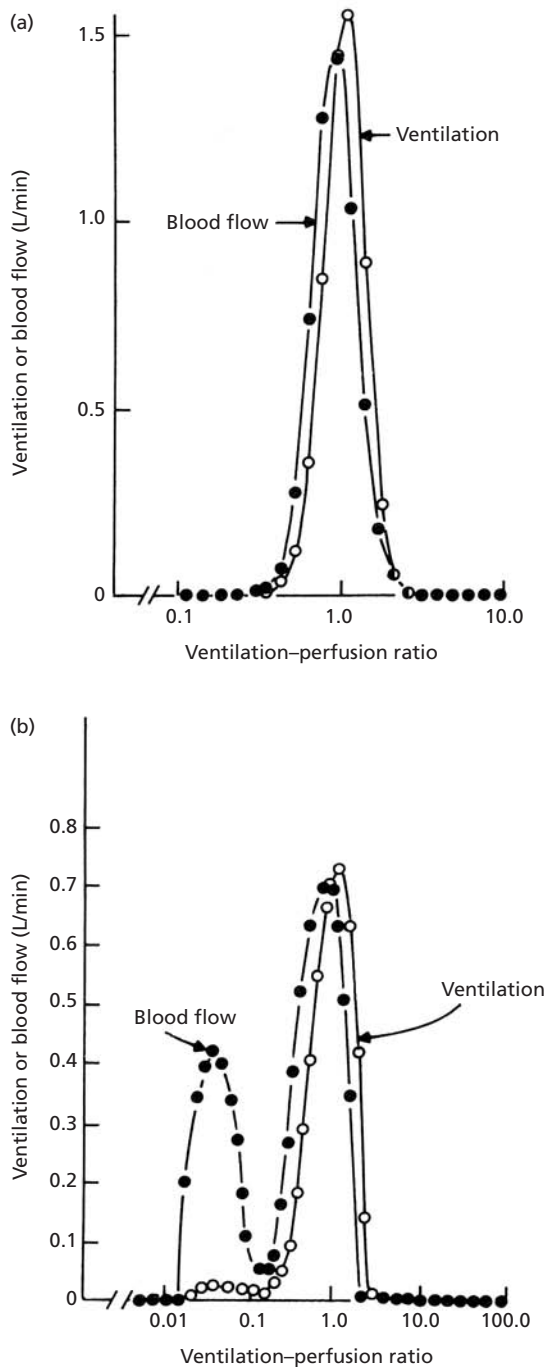

Fig. 2.13 Distribution of ventilation-perfusion ratios measured by the multiple inert gas technique in a normal subject (a) and in a patient with chronic bronchitis and emphysema (b). (From West [38] with permission.)

embolism [40] the associated hypoxaemia can be shown to be due to excessive shunt, although the mechanisms underlying this are unclear. The inert gas elimination technique has now been used to study ventilation-perfusion ratio abnormalities in a range of diseases, including interstitial pulmonary fibrosis [41], asthma [42],

pulmonary vascular diseases [43] and acute respiratory failure [44].

In summary, different  $\dot{V}_A/\dot{Q}$  ratios exist in the normal lung and are reflected in the presence of an alveolar-arterial  $P_{O_2}$  difference. This may be markedly increased in disease. In disease, a large physiological dead space (wasted ventilation) represents an increase in the population of alveoli with high  $\dot{V}_A/\dot{Q}$  ratios; a large physiological shunt represents an increase in the population of alveoli with low  $\dot{V}_A/\dot{Q}$  ratios.

### Measurement of physiological shunt

It is assumed that all of the fall in  $P_{aO_2}$  can be attributed to the addition of mixed venous blood to end-capillary blood. The shunt  $\dot{Q}_s/\dot{Q}_T$  can be calculated using the following equation:

$$\dot{Q}_s/\dot{Q}_T = \frac{C_{CO_2} - C_{aO_2}}{C_{CO_2} - C_{vO_2}} \quad [2.7]$$

where  $C$  represents  $O_2$  content;  $c$ , end-capillary (pulmonary);  $a$ , arterial; and  $v$ , mixed venous. The  $O_2$  content of end-capillary blood is calculated from the  $P_{aO_2}$  and the  $O_2$  dissociation curve [5].

### Causes of hypoxaemia

$\dot{V}_A/\dot{Q}$  abnormality is the commonest cause of hypoxaemia in human lung disease. It must be differentiated from other causes, which include the following.

**1 Hypoventilation:** if alveolar ventilation is halved,  $P_{aCO_2}$  will double. It follows from the alveolar air equation that alveolar and hence arterial  $P_{O_2}$  will fall.

**2 True shunt:** in normal humans, a very small but significant shunt occurs as a result of drainage of part of the bronchial circulation into pulmonary venous blood and also the drainage of coronary venous blood into the left ventricle through the Thebesian veins. In disease, for example pulmonary arteriovenous fistula, larger true shunts may occur and may be revealed by inability to achieve a high arterial  $O_2$  tension when 100%  $O_2$  is breathed, since shunted blood is not exposed to the resulting high  $P_{aO_2}$ .

### Diffusion

#### Factors affecting gaseous diffusion in the lung

By the time inspired gas reaches the alveoli, movement of gas molecules is determined almost entirely by diffusion; this is so efficient that alveolar gas can be considered uniform without the existence of any intra-alveolar gas concentration gradients. Gas transfer across the alveolar wall into the pulmonary capillary involves passage of molecules through the epithelial cell, basement

Fig. 2.14 Components of the diffusing capacity of the lung.

membranes, the interstitium and the endothelial cell and thence through plasma and the red cell membrane to the interior of the red cell (Fig. 2.14). The rate of gas transfer in the lung depends on:

- 1 surface area available for transfer;
- 2 thickness of the alveolar–capillary membrane;
- 3 solubility and molecular weight of the gas concerned:  $\text{CO}_2$  has a similar molecular weight to  $\text{O}_2$  but diffuses about 20 times more rapidly because of its high solubility.

The diffusing capacity ( $D_L$ ) for a gas within the lung can be expressed by the following equation:

$$D_L = \frac{\dot{V}_{\text{gas}}}{P_1 - P_2} \quad [2.8]$$

where  $\dot{V}_{\text{gas}}$  is the volume of gas transferred in unit time and  $P_1$  and  $P_2$  are the pressures of gas in alveoli and capillary blood respectively. Thus the diffusing capacity for carbon monoxide (CO) is defined as:

$$D_{\text{LCO}} = \frac{\dot{V}_{\text{CO}}}{P_1 - P_2} \quad [2.9]$$

and since the  $P_{\text{CO}}$  in capillary blood is usually so small that it can be neglected, Eqn 2.9 can be simplified to:

$$D_{\text{LCO}} = \frac{\dot{V}_{\text{CO}}}{P_{\text{ACO}}} \quad [2.10]$$

It is now agreed that the normal alveolar membrane causes no appreciable impediment to  $\text{O}_2$  diffusion from alveoli to blood [45]. Theoretically, diffusion may be influenced by intra-alveolar oedema or exudate, interstitial oedema, exudate or fibrosis, thickening of the alveolar wall, thickening of the capillary membrane or increase of the intracapillary path for  $\text{O}_2$  due to capillary dilatation. Pulmonary diffusing capacity measures the impediment produced by all the factors involved in transfer of  $\text{O}_2$  to the erythrocyte; for the whole lung the  $\dot{V}_A/\dot{Q}$  ratio is probably

the most important factor. In high  $\dot{V}_A/\dot{Q}$  areas, ventilation is wasted and little or no gas is exchanged in spite of an intact transfer surface leading to a decrease in  $D_{\text{LCO}}$  for the lungs as a whole. There are no methods at present available that can distinguish between  $\dot{V}_A/\dot{Q}$  abnormality and impaired diffusion [46] but the general consensus of opinion is that  $\dot{V}_A/\dot{Q}$  disturbances are more important than thickening of the alveolar membrane [47,48].

### Components of $D_{\text{LCO}}$

A significant part of the diffusion pathway lies between the capillary endothelium and the red cell (see Fig. 2.14). An additional factor that influences diffusion of  $\text{O}_2$  is the rate of the chemical reaction that combines  $\text{O}_2$  with haemoglobin within the red cell. The diffusing capacity can thus be considered as having two components, the first reflecting transfer from the alveolus to the interior of the red cell and the second concerned with the combination of  $\text{O}_2$  with haemoglobin [49]. These two components can be expressed as the inverse of their effective diffusing capacities in the following equation:

$$\frac{1}{D_L} = \frac{1}{D_m} + \frac{1}{\Theta V_c} \quad [2.11]$$

where  $D_m$  is the membrane component of resistance to diffusion,  $\Theta$  describes the rate of reaction of  $\text{O}_2$  with haemoglobin and  $V_c$  is the volume of capillary blood.  $\Theta V_c$  is thus the effective diffusion capacity for the rate of reaction of  $\text{O}_2$  with haemoglobin. These two separate components of the resistance to diffusion can be measured by special methods [49] and are approximately equal.

### Significance of changes in $D_{\text{LCO}}$

From Eqn 2.11 it follows that changes in capillary blood volume can influence  $D_L$ , which in consequence is decreased in anaemia and increased in polycythaemia, left-to-right cardiac shunts, exercise and the supine position. A low value for  $D_L$  may also indicate:

- 1 small lungs or lesions reducing lung volumes, e.g. pneumonectomy;
- 2 obstructive lung disease with non-uniform  $\dot{V}_A/\dot{Q}$  distribution;
- 3 emphysema with decrease of total gas-exchanging area;
- 4 interstitial lung disease with altered ventilation, perfusion and probably diffusion in many areas.

$D_L$  is of particular value in defining abnormality and response to treatment in the interstitial lung diseases, which include fibrosing alveolitis, sarcoidosis, asbestosis, farmer's lung, collagen diseases of the lung and polyarteritis nodosa. In some conditions, e.g. sarcoidosis, changes in  $D_L$  may be a more sensitive indicator of response to treatment than radiological changes.  $D_L$  has also been used (after adjustment for the ventilated lung

volume to give the  $K_{CO}$  as a measure of fresh pulmonary haemorrhage in Goodpasture's syndrome, where increases in  $K_{CO}$  are attributed to uptake of CO by sequestered haemoglobin in the lung [50].

### Methods of measuring $D_L$

Ideally, the gas used for estimations of  $D_L$  should be  $O_2$ , and the relevant equation is:

$$D_{LO_2} = \frac{\dot{V}_{O_2}}{P_{AO_2} - P_{CO_2}} \quad [2.12]$$

where  $P_{CO_2}$  is mean pulmonary capillary pressure. Such measurements are possible [51,52], although because of the difficulty in measuring  $P_{CO_2}$  it is more usual in routine practice to measure  $D_{LCO}$  [48,53,54].

CO has a great affinity for haemoglobin (240 times that of  $O_2$ ). At low alveolar pressures of CO only a small proportion of haemoglobin is saturated with CO during passage through the pulmonary capillaries, so that the  $P_{CO}$  in the blood is small relative to the  $P_{CO}$  in the alveoli. The relatively large difference between  $P_{ACO}$  and  $P_{CCO}$  makes the CO method for measuring diffusion capacity more accurate and reproducible than the  $O_2$  method. In essence the techniques employed require measurement of the uptake of CO ( $\dot{V}_{CO}$ ) and  $P_{ACO}$  by means of an infrared analyser,  $P_{CCO}$  is assumed to be zero and the values are entered into Eqn 2.10.

Simultaneous measurement of alveolar volume by He dilution also allows determination of the transfer coefficient ( $D_{LCO}/V_A$ , or  $K_{CO}$ ), which may be a more appropriate indicator of the effectiveness of gas exchange when lung volume has been lost because of either disease or surgery. Although steady-state measurements of  $D_{LCO}$  are possible [55], they are less reproducible than the single-breath method that is currently the procedure of choice.

## Oxygen and carbon dioxide transport in blood

### Oxygen transport

$O_2$  is carried in blood in two forms, dissolved and in combination with haemoglobin.

#### Dissolved oxygen

For every 1 kPa (7.5 mmHg) of partial pressure, 0.023 mL  $O_2$  is dissolved in 1 dL of blood; arterial blood with a  $P_{AO_2}$  of 13 kPa (97.5 mmHg) therefore contains 0.3 mL/dL, a small amount in relation to the volume of  $O_2$  carried by haemoglobin.

Fig. 2.15 Oxygen dissociation curve: (A, B) a fall in  $P_{AO_2}$  of 5 kPa (40 mmHg) from 13 to 8 kPa (100 to 60 mmHg) produces only a small change in oxygen saturation or content; (B, C) a similar fall in  $P_{AO_2}$  from 8 to 3 kPa (60 to 20 mmHg) produces a much greater change in saturation.

### Bound oxygen: the haemoglobin dissociation curve

The majority of  $O_2$  in the blood is carried bound to haemoglobin, each haemoglobin molecule binding four  $O_2$  molecules. The successive binding of these four  $O_2$  molecules and associated changes in the structure of haemoglobin determine the shape of the haemoglobin dissociation curve (Fig. 2.15), which relates the  $O_2$  content of blood (or percentage saturation of haemoglobin) to the partial pressure of  $O_2$ . In this reaction 1.39 mL of  $O_2$  combines with 1 g of haemoglobin, so that blood with a haemoglobin concentration of 15.2 g/dL that is fully saturated with  $O_2$  contains 21 mL/dL of bound  $O_2$  (cf dissolved  $O_2$ , 0.3 mL/dL).

The shape of the haemoglobin dissociation curve has several important physiological consequences.

1 At normal  $P_{AO_2}$  haemoglobin is about 95% saturated. It follows that a rise in  $P_{AO_2}$  brought about by hyperventilation or breathing  $O_2$ -rich gas makes little difference to the  $O_2$  content of the blood. Only a small increase in bound  $O_2$  and a partial pressure-dependent rise in dissolved  $O_2$  is possible.

2 A fall in  $P_{AO_2}$  from an initially high level has little effect on the arterial  $O_2$  content or saturation, whereas a similar fall in  $P_{AO_2}$  in the middle range produces striking changes in content or saturation (see Fig. 2.15).

### Factors affecting the position of the haemoglobin dissociation curve

A shift of the  $O_2$  dissociation curve to the right (Fig. 2.16) has consequences for the delivery of  $O_2$  to the tissues

**Fig. 2.16** Effect of a rightward shift of the oxygen dissociation curve on oxygen affinity: for a given  $P_{O_2}$  the haemoglobin is less saturated or the  $P_{O_2}$  at 50% saturation ( $P_{50}$ ) is higher.

where  $P_{O_2}$  is low. The resultant decrease in  $O_2$  affinity of the haemoglobin means that, for a given  $P_{O_2}$ , the haemoglobin is less saturated and has therefore released more of the bound  $O_2$ . Any decrease in  $O_2$  affinity is likely to be beneficial for  $O_2$  delivery to the tissues when  $P_{aO_2}$  is normal since, in this situation at the upper end of the dissociation curve, the reverse effect (that  $O_2$  is also taken up less readily in the lungs) is minimal. However, in hypoxia the decreased  $O_2$  affinity limits the uptake of  $O_2$  in the lungs as much as it enhances delivery to the tissues and no advantage accrues.

$O_2$  affinity can be determined *in vivo* and *in vitro* by determining the  $P_{50}$  (the  $P_{O_2}$  at which 50% of the haemoglobin is saturated), the normal value for human blood being 3.5 kPa (26 mmHg). The  $P_{50}$  is increased with a rightward shift of the dissociation curve or a decrease in  $O_2$  affinity.

The main factors influencing  $O_2$  affinity are listed in Table 2.1. A rise in hydrogen ion concentration (the Bohr effect), temperature or  $P_{CO_2}$  (independent of pH) and 2,3-diphosphoglycerate (2,3-DPG) [56] all shift the curve to the right and decrease  $O_2$  affinity, favouring the release of  $O_2$  in the tissues. 2,3-DPG is formed as a product of glycolysis in the red cell and its production is increased by a rise in red cell intracellular pH, which increases the activity of phosphofructokinase.  $O_2$  and 2,3-DPG are com-

**Table 2.1** Some factors influencing oxygen affinity. (Modified from Cumming & Semple [58].)

Decrease in $O_2$ affinity (shift in $O_2$ dissociation curve to right)	Increase in $O_2$ affinity (shift in $O_2$ dissociation curve to left)
Rise in $[H^+]$ (fall in pH) $P_{CO_2}$ and temperature	Fall in $[H^+]$ , $P_{CO_2}$ and temperature
Increase in red cell DPG, ADP, ATP and inorganic phosphates	Decrease in red cell DPG, ADP, ATP and inorganic phosphates
Anaemia	Stored (banked) blood
Residence at high altitude	Fetal blood  Rise in red cell carboxyhaemoglobin and methaemoglobin

DPG, 2,3-diphosphoglycerate.

**Fig. 2.17** Normal oxygen dissociation curve compared with the dissociation curve in the presence of 20% carboxyhaemoglobin. (Modified from Cumming & Semple [58].)

petitive binders for deoxyhaemoglobin and a rise in 2,3-DPG therefore displaces  $O_2$  and reduces  $O_2$  affinity.

CO has an affinity for haemoglobin 240 times that of  $O_2$ . Small concentrations of CO in inspired air may therefore produce high levels of carboxyhaemoglobin (COHb). Heavy cigarette smokers may have as much as 20% of their haemoglobin as COHb [57]. This has two consequences (Fig. 2.17):

- 1 20% of the haemoglobin is not available for binding  $O_2$ ;
- 2 the haemoglobin dissociation curve is shifted to the left with a resultant increase in  $O_2$  affinity.

In hypoxic bronchitic patients such levels of COHb have been shown to limit exercise tolerance [59] and this prob-

ably reflects the resulting impaired delivery of  $O_2$  to the tissues.

$O_2$  delivery to the tissues is not solely a function of the  $O_2$  affinity of haemoglobin. Considerable reserves of  $O_2$  exist in blood as reflected in a mixed venous  $P_{O_2}$  of 5 kPa (37.5 mmHg) (see Fig. 2.4). Mixed venous  $P_{O_2}$  can fall further in association with increased  $O_2$  delivery to the tissues. In addition, increases in tissue blood flow, dependent on assorted mechanisms one of which is a fall in tissue  $P_{O_2}$ , may increase  $O_2$  delivery. Where increases in blood flow are limited, as in cardiac disease, changes in  $O_2$  affinity may well be important.

### Carbon dioxide transport

$CO_2$  produced in tissue cell mitochondria passes rapidly into the blood where it is carried in three forms: (i) dissolved  $CO_2$ , (ii) bicarbonate and (iii) in combination with haemoglobin and other plasma proteins as carbamino compounds.

#### Dissolved carbon dioxide

The amount of  $CO_2$  dissolved in blood is proportional to  $P_{CO_2}$  and is determined by the solubility coefficient of  $CO_2$  (0.225 mmol/kPa). Therefore, at a  $P_{CO_2}$  of 6 kPa (45 mmHg),  $6 \times 0.225 = 1.35$  mmol/L of  $CO_2$  will be carried as dissolved  $CO_2$ , constituting about 8% of the total  $CO_2$  transported in blood [60].

#### Bicarbonate

About 81% of  $CO_2$  carried by blood is carried as bicarbonate [60]. When  $CO_2$  passes from plasma to red cells, the reaction  $CO_2 + H_2O \rightarrow H_2CO_3$  is catalysed by the red cell enzyme, carbonic anhydrase. Carbonic acid rapidly dissociates to  $H^+$  and  $HCO_3^-$  (Fig. 2.18);  $H^+$  is bound by haemoglobin, which acts as a base, and more  $HCO_3^-$  is generated to preserve the constancy of the dissociation coefficient (law of mass action). As a result  $HCO_3^-$  within the red cells exceeds that in plasma and  $HCO_3^-$  is exchanged for  $Cl^-$  across the red cell membrane according to the Gibbs–Donnan equilibrium that preserves electrical neutrality.  $H^+$  binding to haemoglobin is facilitated by deoxygenation of haemoglobin in the tissues (the Haldane effect), thus increasing the capacity of venous blood to carry  $CO_2$ . The process shown in Fig. 2.18 as occurring in the tissues occurs equally rapidly in reverse in the lungs, where  $CO_2$  passes from capillary blood to the alveoli.

#### Carbamino compounds

About 11% of total  $CO_2$  carried in blood is in the form of carbamino compounds, which are formed by the combination of  $CO_2$  with terminal amino groups in blood

Fig. 2.18 Reactions consequent on the release of carbon dioxide from the tissues to the blood. (From Cumming & Semple [58].)

Fig. 2.19 Carbon dioxide dissociation curves for blood of different oxygen saturations. (Modified from West [7].)

protein, the most important of which is haemoglobin, e.g.  $HbNH_2 + CO_2 = HbNHCOOH$ . Reduced haemoglobin can bind more  $CO_2$  than deoxyhaemoglobin so that deoxygenation in the tissue capillaries facilitates  $CO_2$  transport.

#### Carbon dioxide dissociation curve

In comparison with the  $O_2$  dissociation curve, the  $CO_2$  dissociation curve is more linear, i.e. additional  $CO_2$  is carried in blood in proportion to  $P_{CO_2}$  and there is no 'fully saturated' point (Fig. 2.19). More  $CO_2$  is carried by deoxygenated blood for a given  $P_{CO_2}$  as shown in Fig. 2.19.

#### Measurement of blood gas tensions

Clinical estimation of hypoxaemia is rarely accurate and  $O_2$  saturation has to fall below 85% before it can be reliably

appreciated [61], such observations being further confounded by artificial lighting [62].  $O_2$  saturation ( $SaO_2$ ) may be measured by an ear oximeter [63]; this is particularly useful for measuring changes in  $SaO_2$  that may be produced by exercise for example. Transcutaneous monitoring of  $PO_2$  for periods of up to 4 h is possible in infants using a heated polarographic  $O_2$  sensor applied to the skin [64]. Transcutaneous monitoring of  $PCO_2$  has so far proved reliable in a limited number of applications, such as in infants where the duration of application of the sensor is limited to 4 h [65].  $PaO_2$  and  $Paco_2$  are now most commonly measured on samples of arterial blood obtained by puncture of the radial, brachial or femoral arteries and analysed by  $PO_2$ ,  $PCO_2$  and pH electrodes [66], which must be carefully calibrated preferably with tonometered blood [66].

### Acid–base status

The acid–base status of human blood is best considered in the context of the following equation:

$$pH = pK + \log \frac{[HCO_3^-]}{\alpha PCO_2} \quad [2.13]$$

which can be derived from the Henderson–Hasselbalch equation in which  $pK$  is the dissociation constant for carbonic acid and  $\alpha$  is the solubility coefficient of  $CO_2$ . Typical values for this equation are:

$$pH = 6.1 + \log \frac{24}{0.225 \times 5} = 7.40 \quad [2.14]$$

Bicarbonate concentration is chiefly determined by the kidney and the  $PCO_2$  by the lung. Understanding of acid–base disturbance can be helped by the use of an acid–base diagram similar to that shown in Fig. 2.20 [67]. This diagram plots  $Paco_2$  against pH or  $H^+$  concentration; the corresponding  $HCO_3^-$  values, which can be derived from Eqn 2.13, are shown as a fan of isopleths radiating from the origin. The normal range of values is shown by the central square. Five zones are also defined by the 95% confidence limits, representing the five varieties of acid–base disturbance encountered in clinical practice (Fig. 2.20). The limits of these zones were defined by measuring pH and  $Paco_2$  in the following situations.

- 1 Acute respiratory acidosis following acute inhalation of  $CO_2$ -rich gas in normal humans [68].
- 2 Chronic respiratory acidosis in patients with chronic elevation of  $Paco_2$  [69,70].
- 3 Metabolic alkalosis caused by chronic ingestion of sodium bicarbonate [71].
- 4 Respiratory alkalosis in anaesthetized subjects hyperventilated to lower  $Paco_2$  [72].
- 5 Metabolic acidosis in patients with renal failure or diabetic ketoacidosis [73,74].

### Respiratory acidosis

A rise in  $Paco_2$  caused by acute hypoventilation reduces the  $HCO_3^-/PCO_2$  ratio and decreases pH as shown by point 1 in Fig. 2.20; this point lies in the acute respiratory acidosis band. With persistent elevation of  $Paco_2$  the kidneys respond by retaining bicarbonate (over 2–3 days), which tends to restore pH towards normal (point 2 in the chronic respiratory acidosis band in Fig. 2.20). Acute respiratory acidosis may thus be converted, depending on the degree of compensation, to a fully or partially compensated respiratory acidosis.

### Respiratory alkalosis

Hyperventilation, which is seen in many pulmonary diseases, lowers  $Paco_2$ , increases the  $HCO_3^-/Paco_2$  ratio and raises pH (point 3 in Fig. 2.20). If the fall in  $Paco_2$  persists, as it does in high-altitude hyperventilation, renal compensation via excretion of bicarbonate may restore the pH towards normal, i.e. a compensated respiratory alkalosis.

### Metabolic acidosis

Metabolic acidosis is present when a primary fall in  $HCO_3^-$ , such as occurs in renal failure, diabetic ketoacidosis and lactic acidosis, results in a fall in the  $HCO_3^-/Paco_2$  ratio and fall in pH (point 4 in Fig. 2.20). The rise in arterial  $H^+$  stimulates the arterial chemoreceptors, which reflexly increase alveolar ventilation, lower  $Paco_2$  and usually result in partial compensation of the acidosis.

### Metabolic alkalosis

A primary rise in  $HCO_3^-$  may result from excess ingestion of alkalis, diuretic therapy or vomiting of acid gastric juice and is associated with a rise in the  $HCO_3^-/Paco_2$  ratio and pH (point 5 in Fig. 2.20). Respiratory compensation mediated by the central chemoreceptors may occur to a varying degree, giving a full range of compensation from uncompensated to partially or fully compensated metabolic alkalosis.

An example of the use of the acid–base diagram in the assessment of the clinical management of a patient with respiratory disease is shown in Fig. 2.21. A 62-year-old patient with severe chronic bronchitis and emphysema was severely hypoxic ( $PaO_2$  3.7 kPa, 28 mmHg) on admission with an acute exacerbation of his disease. The initial  $Paco_2$  and  $H^+$  values lay between the acute and chronic respiratory acidosis bands (Fig. 2.21). Despite controlled  $O_2$  therapy the  $CO_2$  retention progressed after 24 h so that artificial ventilation was required. This rapidly restored  $Paco_2$  to what was probably his normal level of about 8 kPa (60 mmHg).

Fig. 2.20 The Flenley acid-base diagram relating arterial hydrogen ion concentration to  $\text{PaCO}_2$  with isopleths of bicarbonate concentration and showing the 95% confidence limits for acid-base disorders derived from published work; for explanation of the numbered points see text. (From Flenley [67].)

## Lung mechanics

During inspiration the respiratory muscles work to overcome the elastic recoil of the lungs and thorax, the frictional resistance due to movement of tissues and the resistance to airflow in airways.

### Elastic properties of the lungs and thorax: compliance

If the thorax is opened, the lungs collapse while the chest wall expands to a value above FRC. In life these tendencies are reflected in the presence of a subatmospheric pressure in the intrapleural space, which can be determined approximately by measuring the pressure in a 10-cm long balloon placed in the mid-oesophagus. Elasticity can be measured as the volume change for a given change in pressure applied to the lungs and chest wall together; this measurement, called compliance, is a measure of the distensibility of the system.

### Measurement of compliance

Compliance can be measured under static and dynamic conditions.

### Static compliance

The static compliance of the lungs and chest wall together (total compliance) can be measured by determining the relaxation pressure-volume curve. The subject inspires known volumes from a spirometer and then relaxes with open glottis while airway pressure is measured. The resulting relationship between pressure (atmospheric minus alveolar or airway pressure) and volume is the relaxation pressure-volume curve (Fig. 2.22). If intrathoracic pressure is measured simultaneously, lung compliance alone can be measured (airway pressure – intrapleural pressure) (Fig. 2.22); since these compliances are related as follows

$$\frac{1}{\text{total compliance}} = \frac{1}{\text{lung compliance}} + \frac{1}{\text{chest wall compliance}} \quad [2.15]$$

it is possible to calculate chest wall compliance. The relationships are approximately linear near FRC and normal values are about 0.21 L/cmH<sub>2</sub>O for pulmonary, 0.2 L/cmH<sub>2</sub>O for chest wall and 0.1 L/cmH<sub>2</sub>O for total compliance. Pulmonary static compliance is decreased in

**Fig. 2.21** Serial blood gas values in a middle-aged patient with an acute exacerbation of severe chronic bronchitis on admission (1), 24 h later (2) and after intubation and artificial ventilation (3).

the interstitial lung diseases such as fibrosing alveolitis ('stiff lungs') and increased in emphysema.

### Dynamic compliance

Dynamic compliance of the lung can be measured by plotting intrathoracic pressure against volume on an oscilloscope and drawing a line through the points of no flow (Fig. 2.23). The slope of this line is dynamic compliance, which at normal breathing frequencies is usually identical to the static compliance in normal lungs. In disease dynamic compliance may be lower than static compliance, particularly at high breathing frequencies. This reflects the presence in the lung of units ventilating in parallel at different rates. Units with a low resistance or compliance (fast alveoli) are preferentially ventilated when insufficient time is available for slow alveoli to fill. Measurements of compliance reflect the behaviour of the fast alveoli in this situation and are therefore low. When dynamic compliance decreases, with increasing frequency of breathing, compliance is said to be frequency dependent. Measurement of frequency dependence of compliance has been suggested as a sensitive test for detection of early abnormalities of lung function [75].

### Surfactant

The pressure-volume curve for static points during inflation of the lungs from FRC differs from that on deflation (Fig. 2.24), a finding known as hysteresis that occurs in most elastic materials. However, if the lungs are inflated and deflated with saline, which abolishes surface tension forces, the lungs become more compliant and the hysteresis effect is reduced [76] (Fig. 2.24). The difference between the air and saline pressure-volume curves is now thought to be due at least partly to surfactant, a phospholipid moiety [77] synthesized in the type II pneumocyte, which has the unique property of lowering surface tension in the alveoli where it is produced and thus diminishing the likelihood of alveolar collapse.

Synthesis of surfactant begins at approximately 16–18 weeks of gestation. It is stored in the alveolar cell until 26 weeks when release on to the alveolar surface occurs, although quantities sufficient to prevent the development of hyaline membrane disease are not present until later in gestation [78]. More than 70% of infants born at 29 weeks of gestation develop respiratory distress syndrome compared with only 8–10% of those born at 35 weeks of gestation [79]. Fetal lung maturity can be determined

Fig. 2.22 Relaxation pressure-volume curve of the lungs and chest wall shown separately and together. (Modified from West [7].)

Fig. 2.23 Relationship of lung volume above functional residual capacity to intrapleural pressure during quiet breathing; dynamic compliance is the slope of the line ABC.

antenatally by measurement of the amniotic fluid lecithin/sphingomyelin ratio [80] or the amniotic fluid foam test [81]. Not only are quantitative differences in lung surfactant present in premature babies but qualitative differences are also found. In hyaline membrane disease, surfactant has a relative increase in unsaturated fatty acids (increase in oleic acid and decrease in palmitic

Fig. 2.24 Inflation (open circle) and deflation (black circle) pressure-volume curves of cat lungs with air and saline. (Modified from West [7].)

acid) [82] that returns to normal as recovery occurs. In addition to impairing surface activity, the relative increase in unsaturated fatty acids may increase substrate susceptibility to oxidation by highly toxic endoperoxides. Such endoperoxides may contribute to the pathogenesis of the chronic fibrotic lung disorder termed bronchopulmonary dysplasia, which is seen in some of the infant survivors of hyaline membrane disease [83].

The pathology of hyaline membrane disease in infants, where compliance is low, alveoli are collapsed and fluid transudes into the alveolar spaces, is also seen in the adult respiratory distress syndrome where surfactant deficiency has also been demonstrated [84,85]. Replacement of surfactant by intratracheal instillation appears to be of benefit in hyaline membrane disease [86].

### Airways resistance

Tissue resistance contributes less than 20% of the total resistance to flow in the lungs of a normal subject and although it may be increased in lung disease the majority of the resistance to airflow resides in the airways, the airway resistance (AWR). When flow occurs through a tube, the pressure difference between the ends of the tube is related to flow by a relationship of the form:

$$P = k_1 V + k_2 V^2 \quad [2.16]$$

where the first term indicates a contribution from laminar flow and the second from turbulent flow in the airways. In laminar or streamlined flow, which occurs in the smaller airways in the lung, Poiseuille's equation for flow in straight circular tubes applies:

$$\dot{V} = \frac{\pi P r^4}{8 \eta l} \quad [2.17]$$

where  $P$  is the pressure difference,  $r$  the radius of the tube,  $\eta$  the viscosity of the gas and  $l$  the length of the tube. Since resistance is pressure divided by flow it follows that:

$$R = \frac{8\eta l}{\pi r^4} \quad [2.18]$$

an equation that emphasizes the importance of airway radius: resistance is increased 16-fold if radius is halved.

In turbulent flow, which occurs in larger airways particularly at high flow rates, the pressure difference is proportional to the square of flow and viscosity is no longer important. However, in turbulent flow gas density becomes important and the pressure difference for a given flow is reduced by lowering gas density, e.g. by breathing He/O<sub>2</sub> mixtures. Much of the flow in the lung is probably intermediate or transitional between laminar and fully developed turbulent flow, hence the need to recognize contributions from both to the pressure difference along the airways.

### Sites of airways resistance

By passing catheters into the airways to measure pressure in the lumen it is possible to determine the contribution to total airways resistance from airways of different sizes [87]. Such studies have shown that most of the resistance to airflow arises in medium to large airways in the lung (Fig. 2.25) and that the smaller airways of <2 mm in diameter contribute rather less than 10% to total airways resistance. This would be expected from the differences in total

Fig. 2.25 Contribution of different-sized airways to airway resistance: most resistance resides in intermediate-sized bronchi and very little in the small airways. (Modified from West [7].)

cross-sectional area at different levels of the respiratory tract (Fig. 2.26). Disease in small airways may be severe before airways resistance is significantly changed, and hence the development of other tests of 'small airways' function such as He/O<sub>2</sub> flow-volume curves, the maximum mid-expiratory flow rate and frequency dependence of compliance [88,89].

### Factors affecting airways resistance

Airways resistance may be increased because of encroachment on the airway lumen either by mucus or by inflammation or oedema of the airway wall. In asthma or bronchitis and in normal subjects exposed to irritant aerosols [90], bronchial smooth muscle tone is increased with reduction in airway calibre. Mast cell mediators of asthma such as leukotrienes and histamine are not only potent bronchoconstrictors in humans [91] but also increase mucus secretion [92] and cause inflammation [93], with resultant airway narrowing. The airways are also dependent on lung parenchyma for support by traction; thus in emphysema, where parenchyma is destroyed, airways resistance is increased. Finally, airways resistance is dependent on the lung volume at which it is measured, as shown in Fig. 2.27 where resistance and its reciprocal, airways conductance, are plotted against lung volume.

Fig. 2.26 Increase in total cross-sectional area of the airways with succeeding generations of airways. (Modified from West [7].)

Fig. 2.27 Relationship of airways resistance (AWR) and conductance to lung volume. (Modified from West [7].)

### Measurement of airways resistance

Airways resistance can be calculated from measurements of atmospheric and alveolar pressures and flow. Flow is measured with a pneumotachograph and alveolar pressure with a body plethysmograph using an interrupter technique [94]; normal values are around 1–3 cmH<sub>2</sub>O/L/s with average flow rates. Alternatively, airways resistance can be measured by the simple, non-invasive forced oscillation technique, which does not require the cooperation of the patient [95].

### Other tests for airways obstruction

#### Dynamic lung volumes

A more commonly used index of increased airways resistance or airways obstruction is the forced expiratory volume in 1 s (FEV<sub>1</sub>) and its ratio to the forced vital capacity (FVC). The latter is the volume expired with the greatest force and speed from TLC and the former the volume expired in 1 s during the same manoeuvre (Fig. 2.28). The FEV<sub>1</sub> was initially used as an indirect method of estimating its predecessor as the principal pulmonary function test, the maximal breathing capacity. In normal young and middle-aged adults the FEV<sub>1</sub>/FVC ratio is usually above 75%; in childhood it may be higher, even approaching 100%; while in the elderly values of 70–75% are commonly found. A reduction in the FEV<sub>1</sub>/FVC ratio indicates airways narrowing, the severity of which is best indicated by the absolute value of FEV<sub>1</sub> (Fig. 2.28). Predicted values for these measurements based on height, age and sex have been published by a number of workers [96–99]. An example of the related abnormalities in tests of lung func-

tion in airways obstruction is given in Table 2.2. Airways obstruction is usually reversible to some extent following administration of a  $\beta$ -adrenergic bronchodilator aerosol, increases of greater than 20% in FEV<sub>1</sub> favouring a diagnosis of asthma rather than chronic bronchitis and emphysema. In restrictive lung diseases, such as fibrosing alveolitis, the FEV<sub>1</sub> and FVC are reduced in parallel (the restrictive pattern) (Fig. 2.28). Other changes in tests of lung function that may be found in restrictive lung disease are also shown in Table 2.2.

#### Maximum expiratory flow–volume curve

An alternative way of looking at forced expiration is to measure both expiratory flow and the volume expired, and plot flow against volume to give a maximum expiratory flow–volume curve (Fig. 2.29). The maximum flow obtained, also called the peak expiratory flow rate (PEFR), can be measured from such a curve. The peak flow occurs at high lung volumes (Fig. 2.29) and is effort dependent. Flow at lower lung volumes is effort independent, i.e. increases in effort above a certain level produce no further increase in flow due to the presence of dynamic compression of large airways (see below) at lower lung volumes. Thus flow at lower lung volumes depends on the elastic recoil pressure of the lungs and the resistance of the airways upstream or distal to the point at which dynamic compression occurs [100]. Changes in flow on this part of the flow–volume curve therefore represent changes in either the recoil pressure of the lung (e.g. decreased in emphysema) or the resistance of the smaller airways.

**Fig. 2.28** Measurement of forced expiratory volume in 1 s ( $FEV_1$ ) and forced vital capacity (FVC) in (a) a normal subject, (b) a patient with obstructive lung disease and (c) a patient with restrictive lung disease.

**Fig. 2.29** Maximum expiratory flow-volume (MEFV) curve. The subject expires forcibly from total lung capacity down to residual volume and measured expiratory flow rate is plotted against measured volume. Peak expiratory flow (PEF),  $MEF_{50}$  and  $MEF_{10}$  are indicated by arrows (see text).

Measurements of flow at low lung volumes, e.g. 50, 25 or 10% of VC ( $MEF_{50}$ ,  $MEF_{25}$ ,  $MEF_{10}$ ), are often used as indices of peripheral or small airways resistance and may be less than predicted [101] when the  $FEV_1$  and PEF are normal [102].

### Upper airways obstruction

In upper airways obstruction, characteristic changes are seen on expiratory and inspiratory flow-volume loops depending on the site of the obstruction (Fig. 2.30). In

**Fig. 2.30** Maximum expiratory and inspiratory flow loops in (a) extrathoracic large airway narrowing and (b) intrathoracic tracheal narrowing.

extrathoracic large airway narrowing, inspiratory flow is impaired more than expiratory and an inspiratory flow plateau is usually seen (Fig. 2.30a). In intrathoracic large airway obstruction, expiratory flow is impaired more than inspiratory flow and an expiratory plateau is usual (Fig. 2.30b).

**Fig. 2.31** Peak expiratory flow chart recorded 6-hourly over 4 days in an asthmatic patient. A marked diurnal variation is seen with the lowest values recorded in the early morning, the 'morning dipper' pattern.

### Peak expiratory flow rate

PEFR may be simply measured using equipment such as the Wright peak expiratory flow meter. The machines are cheap and portable and serve a variety of functions. Variability in PEFR of greater than 15–20% in a single day or from day to day is very suggestive of asthma, as shown in Fig. 2.31 where the 'morning dipper' pattern of variation in airways obstruction is illustrated [103]. Most normal subjects demonstrate less than 10% variation in PEFR over a 24-h period [104]. Similarly, PEFR may be used as an index of response to treatment in asthma, as shown in Fig. 2.32 where serial measurements of PEFR in a patient admitted to hospital with acute severe asthma are recorded. Finally, PEFR is the most convenient measurement for use in the diagnosis of exercise-induced asthma, where a fall in PEFR of greater than 15% following exercise is considered diagnostic (Fig. 2.33).

### Dynamic airways compression

Dynamic airways compression is illustrated in Fig. 2.34, where the driving force of the respiratory muscles is represented by a piston compressing the lungs, shown as a single alveolus and airway within a somewhat expanded pleural space. Figure 2.34(a) shows the static situation with no flow and therefore no pressure gradient in the airways. The intrapleural pressure of  $-10\text{cmH}_2\text{O}$  represents the static recoil pressure of the lungs or the tendency of the lungs to collapse. In forced expiration (Fig. 2.34b) a driving pressure of  $20\text{cmH}_2\text{O}$  raises alveolar pressure to  $20\text{cmH}_2\text{O}$  and intrapleural pressure to  $10\text{cmH}_2\text{O}$ . Flow occurs in the airways where pressure drops from  $20\text{cmH}_2\text{O}$  in the alveolus to  $0\text{cmH}_2\text{O}$  in the mouth. At some point along the airway, airway pressure equals intrapleural pressure and downstream from this equal pressure point (X in Fig. 2.34) airway compression tends to

occur. Compression or collapse is not permanent because transient occlusion of the airway results in a rise in upstream airway pressure to alveolar pressure as soon as flow is abolished, with prompt resumption of flow; the airways thus tend to vibrate at the point of dynamic compression. Since the elastic recoil pressure of the lungs decreases with decreasing lung volume (Fig. 2.35), the collapse point moves distally (or upstream) to the smaller airways as forced expiration proceeds.

### Helium breathing

Flow in the larger airways is turbulent but is laminar in the smaller airways where the total cross-sectional area is increased. The smaller airways contribute less than 20% to airway flow resistance and thus the determination of changes affecting these airways is difficult. One method, as above, is to look at flow at low volumes on an expiratory flow–volume curve. Another is to study the effect of breathing 80% He/20%  $\text{O}_2$  mixtures on the shape of the flow–volume curve.

An 80% He/20%  $\text{O}_2$  mixture is much less dense than air. Where turbulent flow occurs, flow is dependent on gas density whereas laminar flow is unaffected. Therefore in subjects with disease of small airways the flow–volume curve changes less than in normal subjects when He/ $\text{O}_2$  mixtures are breathed (Fig. 2.36). Partial expiratory flow–volume curves, e.g. to 60% VC, may be used to avoid the inhibition of vagal tone that occurs with a full inspiration [105]. Indices that have been used to reflect this He effect are the differences in flow rate at 50% VC ( $\Delta V_{50}$ ) between air and He/ $\text{O}_2$  mixtures and the volume at which the two curves are superimposed (the volume of isoflow) [106]. Using this technique the predominant site of airway obstruction in patients with asthma has been classified as either peripheral or central [107].

**Fig. 2.32** Peak expiratory flow rate (PEFR) of a middle-aged patient recovering (with treatment) from acute severe asthma. Note the initially very low values ( $<60$  L/min), the very slow rate of recovery and the emergence of the 'morning dipper' pattern as PEFR improves.

**Fig. 2.33** Serial peak expiratory flow rate measurements taken during 6 min of stair-running exercise and for 1 h in a 14-year-old asthmatic boy to illustrate the time-course of exercise-induced asthma.

### Closing volume

The closing volume is defined as the lung volume at which airways begin to close in the dependent zones of the lungs [108]; this is the volume of gas that can be breathed out to RV after the onset of airway closure. The total volume of gas within the lung at the onset of airway closure is the closing capacity (which equals closing volume + RV).

When a healthy subject in the upright position takes a deep breath from RV, gas initially goes predominantly to the upper zones of the lungs. During the subsequent expiration these zones empty last, i.e. 'first in, last out' [109,110]. This phenomenon may be attributed to airway closure in the dependent lung zones at low lung volumes, i.e. near RV, as the pleural pressure rises above the

**Fig. 2.34** Dynamic compression of airways on forced expiration: intrapleural, alveolar and airway pressures while resting at FRC (a) and during forced expiration (b). Pressures expressed as cmH<sub>2</sub>O; see text. (Modified from Bouhuys [101].)

critical closing pressure of the airways. Early in inspiration from RV, therefore, the 'closed' dependent lung zones do not receive an inspired bolus, which goes predominantly to the upper zones and these consequently have a higher concentration of any tracer gas added to the inspired air.

The test involves the inspiration of a bolus of marker gas from RV to TLC at a rate of less than 0.5 L/s and the subsequent monitoring of the concentration of marker gas during slow exhalation to RV, the concentration being displayed against a simultaneous measure of expired gas volume on an *x-y* recorder. An abrupt change in concentration of marker gas is observed towards the end of expiration and this marks the point from which closing volume is measured (Fig. 2.37). In sitting, normal young subjects

airway closure in the dependent lung zones occurs at lung volumes below about 40% TLC [108].

Loss of elastic recoil of the lung due to ageing means that closure occurs at progressively higher lung volumes, which may encroach on tidal volume breathing. Obesity, ascites and pregnancy, by reducing lung volume, may also cause airway closure during tidal volume breathing. Closing volume may also be increased in chronic bronchi-

tis, asthma [111], increased left atrial pressure (as in mitral stenosis and left ventricular failure) and reduced plasma osmotic pressure (as in cirrhosis). Increased left atrial pressure or reduced osmotic pressure presumably act by causing a cuff of fluid to surround the terminal airways. These effects on closing volume may offer an explanation for the 'bronchitic' features of mitral stenosis, which may disappear after valvotomy, and for the 'asthmatic' component that dominates the early clinical picture of pulmonary oedema.

### Work of breathing

The work done to move the lungs and thoracic cage can be expressed by the product of pressure and volume changes

**Fig. 2.35** Static recoil curve of the lungs: intrapleural pressure is more negative as lung volume increases.

**Fig. 2.36** Flow-volume curves breathing air (broken line) and 80% helium/20% oxygen (solid line) in (a) a normal subject and (b) a patient with airways obstruction predominating in small airways.

**Fig. 2.37** Diagrammatic representation of the components of the closing volume. There are four phases: phase 1 is caused by the emptying of the dead space of apparatus and upper airways; phase 2 shows the rise in concentration of marker gas as alveolar emptying begins; phase 3 is the 'alveolar plateau', due to the mixing of marker gas and air from all regions of the lungs; and phase 4 shows the terminal rise in marker gas concentration when emptying ceases from the lower zones where marker gas concentrations are lower. See text for definitions.

**Fig. 2.38** Lung pressure–volume loops in (a) normal lung, (b) increased airways resistance and (c) decreased lung compliance showing the relative effects of work done against elastic ( $W_E$ ) and resistance ( $W_R$ ) forces; see text for explanation.

during inspiration and expiration and can be illustrated by pressure–volume curves (Fig. 2.38a), where intrathoracic pressure is plotted against lung volume. Areas in such a diagram represent products of volume and pressure and therefore work. The slope of the line AB represents compliance and the area ABC the elastic work done. On inspiration, work is done to overcome tissue and airways resistance as represented by area ABD. When airways resistance increases, the loop widens (Fig. 2.38b) and the area representing work done against resistance increases. Similarly, if compliance is low (Fig. 2.38c) work done against elastic forces, represented by area ABC, is increased.

### Metabolic cost of breathing

The energy requirements for ventilation of the lungs can be determined by measuring the increase in  $O_2$  consumption that results from a given increase in ventilation during, for example, voluntary hyperventilation. At rest in health, the  $O_2$  cost of breathing is about 2% of the total  $O_2$  consumption and this increases at increasing levels of ventilation (Fig. 2.39). In disease, the  $O_2$  cost of breathing may be considerably increased as a result of the increase in mechanical work required to move the lungs (Fig. 2.39), and a situation may arise where the  $O_2$  cost of increased ventilation encroaches upon the extra  $O_2$  absorbed from the lungs as a result of the increased ventilation, so contributing to respiratory failure.

### Respiratory muscle weakness and fatigue

The important respiratory muscles are the diaphragm, intercostal muscles and muscles of the abdominal wall. Unilateral paralysis of the diaphragm is common, easily

**Fig. 2.39** Energy cost of breathing for different levels of pulmonary ventilation in a normal subject and a patient with chronic lung disease. (From Cotes [1].)

suspected on chest radiography and confirmed by fluoroscopy; it usually causes little clinical or physiological abnormality. However, bilateral paralysis or weakness of the diaphragm [112], which may be seen in motoneurone disease, myopathies, myasthenia, polyneuritis, following trauma and in systemic lupus, results in striking orthopnoea and paradoxical inward movement of the abdominal wall during inspiration. Global weakness of the respiratory muscles may occur in motoneurone disease, myasthenia or Guillain–Barré syndrome.

Measurement of the maximal mouth pressure generated by a patient inspiring against an obstruction from RV or expiring against an obstruction from TLC is a useful index of inspiratory or expiratory muscle weakness. Generated pressures of 80 cmH<sub>2</sub>O should be achieved by normal subjects. Where muscle weakness is established and may be progressive, serial measurements of VC are invaluable indications of deterioration and the need for assisted ventilation (Fig. 2.40).

**Fig. 2.40** Serial measurements of vital capacity in a patient with myasthenia gravis: the improvement in vital capacity following neostigmine and edrophonium are well shown. (From Harrison *et al.* [113].)

**Fig. 2.41** Examples of low-frequency fatigue induced in the sternomastoid muscle showing force generated in response to stimulation before (open circle;) and after (black circle;) (a) inspiratory loading and (b) sustained maximum voluntary ventilation. (Modified from Moxham *et al.* [114].)

Fatigue of skeletal muscles may result from repeated high-load muscle contractions and can be demonstrated by the change in shape of the stimulation frequency–force curve. Of particular interest is low-frequency fatigue, which results in a reduction of force generated at low stimulation frequencies and which can persist for hours (Fig. 2.41). Since the firing frequency of motoneurons during everyday activities is low (5–30 Hz), this form of fatigue is of particular physiological importance.

In normal subjects, inspiratory loading and sustained maximal voluntary ventilation can produce low-frequency fatigue of the sternomastoid and the diaphragm [114,115]. In patients with chronic airflow obstruction, sustained maximal voluntary ventilation causes marked low-frequency fatigue of the sternomastoid muscle [116] and presumably also of the diaphragm. Such fatigue may be of considerable clinical importance in view of the stresses imposed upon the respiratory muscles by pulmonary disease. The finding of reduced ventilatory responses to

inhaled  $\text{CO}_2$  caused by fatigue of the respiratory muscles supports this suggestion [117].

Simple tests for detecting respiratory muscle fatigue are not available at present. However, in situations where low-frequency fatigue is likely to occur due to markedly increased work of breathing, therapy should be directed to reducing the work of breathing. The bronchodilator aminophylline may have the independent effect of improving the force-generating properties of the diaphragm in normal humans [118]. Finally, an important contribution of assisted ventilation may be that it rests the respiratory muscles long enough for low-frequency fatigue to resolve.

### Inhalation challenge tests

Specific bronchial challenge testing, e.g. with allergens causing acute asthma, has been used for many years as a research rather than a clinical investigation. Its use should

continue to be restricted to major centres with the necessary expertise, not least because the procedures may be hazardous in inexperienced hands [119].

In contrast, non-specific bronchial challenge testing is being increasingly and probably excessively used in the diagnosis and assessment of patients with asthma or airways disease. Asthmatic subjects are more sensitive than non-asthmatic subjects to the bronchoconstrictor effects of a wide range of chemical agents. This 'reactivity' can be formally assessed by measuring the effect of inhaling increasing doses of bronchoconstrictor agonists, such as histamine or methacholine, on pulmonary function, for example  $FEV_1$ . The most commonly used standardized technique was described by Cockcroft *et al.* [120] and involves delivering nebulized histamine or methacholine in doubling doses each given during 2 min of tidal breathing with measurement of  $FEV_1$  between doses. The test is stopped when there is either a 20% or greater fall in  $FEV_1$  or when the highest concentration of agonist is reached. The level of non-specific reactivity is calculated as the concentration of inhaled agonist that results in a 20% fall in  $FEV_1$  ( $PC_{20}$ ). The  $PC_{20}$  for histamine is usually lower than 8 mg/mL in asthmatic patients and may be as low as 0.1 mg/mL in severe asthma. Normal subjects usually have  $PC_{20}$  values greater than 16 mg/mL; patients with chronic bronchitis, bronchiectasis and other airway diseases may have intermediate values.

Occasionally, determination of non-specific bronchial reactivity will be of supportive diagnostic value, for example in cases of asthmatic cough in patients with normal pulmonary function. The test has no demonstrable contribution to make to the management of patients who are already known to have asthma.

## Control of breathing

### Central nervous mechanisms

The organization of the central nervous control mechanisms for ventilation is still being extensively investigated [121]. Animal studies have shown that there are cells in the pons and medulla that discharge in phase with expiration and inspiration, as well as cells which discharge during the switch from one state to the other, so-called phase-spanning cells [122,123]. Inspiratory phase-spanning and expiratory cells, which are found in the rostral pons in the pneumotaxic centre, are believed to influence the timing of respiration by providing an input to rhythmically discharging cells at another site. The apneustic centre, caudal to the pneumotaxic centre in the pons, was originally defined when ablation of the latter in the presence of sectioned vagi resulted in apneustic, or gasping, inspiration in anaesthetized cats. However, in awake cats normal rhythmic respiration occurs even in the absence of the pneumotaxic centre and vagal input, indicating that only

an intact pons and lower medulla are necessary for normal respiratory rhythm [124]. Following pontomedullary section, rhythmic respiration is again found, indicating that rhythm generation originates in the medulla or medullary centres.

In the medulla, two major groups of cells active in phase with respiration have been identified. The dorsal respiratory group, located on the ventrolateral nucleus of the tractus solitarius, contains predominantly inspiratory cells and projects to inspiratory motoneurons in the spinal cord. The ventral respiratory group, associated with the nucleus ambiguus and the nucleus retroambiguus, contains both inspiratory and expiratory cells and projects to inspiratory and expiratory motoneurons in the spinal cord [125]. The rhythmicity of respiration is believed to depend upon inhibitory and excitatory interactions between these various respiratory cells in the medulla. Many other factors influence their activity, including neural inputs from higher centres, chemoreceptors and the vagus nerve.

The brainstem control mechanisms can be considered as an involuntary system designed to regulate ventilation so that  $Paco_2$  is kept constant. Voluntary respiratory activities, such as talking, singing and playing a wind instrument, are possible because the cerebral cortex can temporarily override these mechanisms.

### Higher centres

Electrical stimulation of the cerebral cortex has shown that most areas are inhibitory to respiration, although some motor and premotor areas may be excitatory. Cortical impulses interact with the medullary neuronal network and also descend directly to the spinal cord via the corticobulbar and corticospinal pathways to mediate voluntary respiratory activities.

### Chemoreceptors

#### Carotid chemoreceptors

The carotid bodies, which are situated at the bifurcation of the common carotid arteries, have the highest blood flow per gram of tissue of any organ in the body and are thus uniquely qualified to 'taste' the chemical composition of arterial blood. By altering the chemical composition of arterial blood in an isolated carotid body in animals it has been established that hypoxaemia, hypercapnia and acidosis can increase carotid body nerve discharge and reflexly increase ventilation via an action on the medullary centres [126,127]. The principal stimulus appears to be a fall in  $Pao_2$ ; following bilateral carotid body resection in humans the increase in ventilation caused by hypoxia is abolished, whereas only about 20% of the increase in ventilation due to hypercapnia is abolished [128]. The carotid

**Fig. 2.42** Relationship between pulmonary ventilation and (a) end-tidal  $P_{O_2}$  and (b) arterial oxygen saturation when isocapnic progressive hypoxia is induced over a period of 15 min.

body response to hypoxia is increased in hypercapnia [126].

The ventilatory response to hypoxia in normal humans can be measured by recording ventilation while  $P_{aO_2}$  is reduced by the addition of  $N_2$  to inspired air,  $CO_2$  also being added as required to offset the resulting fall in  $P_{aCO_2}$  [129]. The degree of hypoxia can be measured either as end-tidal (approximately alveolar)  $P_{O_2}$  measured at the mouth with an  $O_2$  analyser or as  $Sa_{O_2}$  measured with an ear oximeter. Typical normal relationships between ventilation,  $P_{O_2}$  and  $Sa_{O_2}$  are shown in Fig. 2.42. The relationship between ventilation and  $P_{O_2}$  is curvilinear, greater increases in ventilation resulting from a fixed fall in  $P_{O_2}$  at lower  $P_{O_2}$  values; the ventilation/ $Sa_{O_2}$  relationship is linear, a logical consequence of the shape of the haemoglobin dissociation curve.

Using methods such as this, a range of normal values for the ventilatory response to hypoxia have been established [130]. The hypoxic drive diminishes with age [131] and has a genetic component [132]. Impaired hypoxic responsiveness has been implicated in chronic mountain sickness [133], the obesity alveolar hypoventilation syndrome [134] and possibly in the pathogenesis of some cases of the 'blue and bloated' syndrome in chronic bronchitis [135]. However, most patients with severe hypercapnic respiratory failure are dependent on their hypoxic drive to continue breathing. Abolition of this drive by inappropriate increases in  $P_{aO_2}$  resulting from  $O_2$  therapy may result in death from  $CO_2$  narcosis secondary to the resulting hypoventilation [136].

### Central chemoreceptors

The  $P_{CO_2}$  of arterial blood is regulated within very narrow limits in humans both at rest and during exercise. Studies in animals have revealed areas on the ventral surface of the medulla that, when stimulated by applications of  $CO_2$  or  $H^+$ -rich fluid or by appropriate changes in the bathing cerebrospinal fluid (CSF), produce an increase in ventilation [137]. These areas, which are remote from the phasi-

cally firing respiratory cells of the medulla, have been designated the central chemoreceptors and are influenced by changes in  $P_{CO_2}$  and  $H^+$  concentration of both arterial blood and CSF. They probably mediate 80% of the increase in ventilation that results from an increase in  $P_{aCO_2}$ .

$CO_2$  diffuses rapidly across the blood-brain barrier from blood to CSF; since CSF is relatively unbuffered compared with blood, an increase in  $P_{CO_2}$  results in a greater decrease in CSF than arterial pH. The resultant hyperventilation lowers  $P_{CO_2}$  and restores arterial and CSF pH towards normal. Studies in animals where  $CO_2$  has been totally removed from blood perfusing the brain have shown that even in the awake animal prolonged apnoea results, suggesting that the medullary centres are dependent on a tonic input from the central chemoreceptors to maintain rhythmic respiration [138].

The sensitivity of the central chemoreceptors to increases in  $P_{CO_2}$  can be assessed by measuring the increase in ventilation that results when  $P_{CO_2}$  is increased by adding  $CO_2$  to inspired gas [139], while  $P_{O_2}$  is maintained above 30 kPa (225 mmHg) to abolish the peripheral chemoreceptor contribution [140]. Figure 2.43 shows the range of normal ventilatory responses to  $CO_2$ . The response decreases with age [131] and has a genetic component [132]. The ventilatory response to  $CO_2$  may be decreased by tranquillizer, sedative or narcotic drugs to such an extent that  $CO_2$  retention occurs [141]. Finally, the  $CO_2$  response is diminished in severe chronic airways obstruction, where the increased work of breathing as well as a true fall in central chemoreceptor sensitivity are probably both factors [142].

### Vagal reflexes

#### Pulmonary stretch receptors

There are three reflexes thought to be mediated by stretch receptors located in the bronchi and bronchioles: the inflation reflex (Hering-Breuer reflex), the deflation reflex and the paradoxical reflex of Head.

**Fig. 2.43** Relationship between ventilation and  $P_{aCO_2}$  during carbon dioxide rebreathing in hyperoxia: the two lines represent the extremes of the normal range of response.

### *Inflation reflex*

In 1868 Hering [143] and Breuer [144] showed that maintained inflation of the lungs decreased the frequency of inspiratory efforts in anaesthetized animals and that maintained collapse had the reverse effect. Vagotomy prevents these responses, proving that they are reflex. The vagal afferent input inhibits the discharge of the inspiratory cells of the dorsal respiratory group and hence inspiration. The reflex is present in the human newborn [145] but can only be demonstrated in adults under anaesthesia and only then when inflation volumes of over 800 mL are used [146]. Since this volume exceeds the usual tidal volume at rest, this reflex is not a factor in ordinary quiet breathing.

### *Deflation reflex*

Deflation of the lungs stimulates breathing in animals by a reflex action mediated by stretch receptors [147]. The reflex is unlikely to be active in ordinary breathing but may stimulate the rate and force of inspiration in pneumothorax or atelectasis.

### *Head's paradoxical reflex*

In 1889, Head [148] showed that inflation of the lungs of rabbits when the vagus nerve was partially blocked (during recovery from freezing) gave no inflation reflex but instead resulted in a prolonged and vigorous contraction of the diaphragm. Two observations have suggested possible physiological roles for this paradoxical reflex. The occasional deep breaths that punctuate ordinary quiet breathing [149], which are believed to prevent the microatelectasis that would otherwise occur, disappear

after vagotomy and it has been suggested that they may be due to the paradoxical reflex [150]. Cross and his colleagues [145] observed gasps when the lungs of newborn babies were inflated during the first 5 days. They have suggested that the mechanism is analogous to the paradoxical reflex and that it may promote aeration of the neonatal lung.

### **J receptors**

The prime physiological stimulus to the juxtapulmonary capillary or J receptors is pulmonary congestion, i.e. increase in pulmonary capillary pressure [151,152]. J receptors are responsible for rapid shallow breathing when stimulated by pulmonary congestion and oedema, microembolism and inhalation of certain chemical substances [153]. Other reflex effects of J receptor stimulation are hypotension, bradycardia and marked expiratory narrowing of the larynx. The latter occurs typically in newborn infants with respiratory distress and may explain the expiratory grunting that characterizes the condition.

### **Pulmonary irritant receptors**

Receptors lying in the bronchial epithelium have been shown in animals to discharge in response to irritant gases (smoke,  $SO_2$ , etc.), lung collapse and a variety of other pulmonary insults resulting in reflex bronchoconstriction [154,155] and hyperventilation. Stimulation of these receptors may cause acute asthmatic attacks in susceptible individuals.

### **Cough receptors**

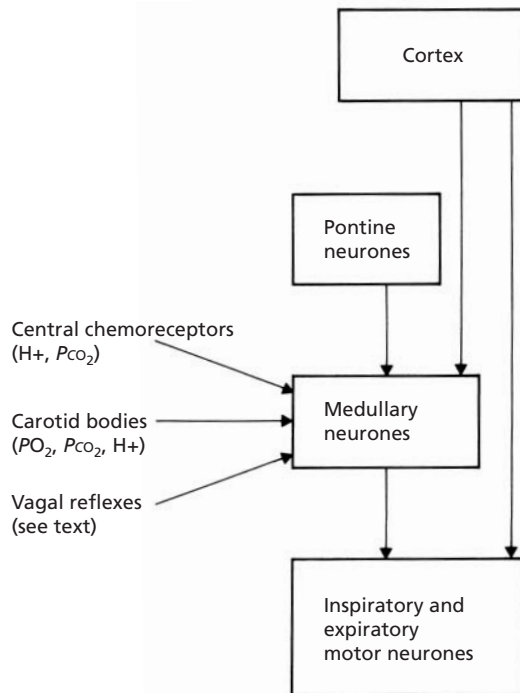

Receptors lying in the large airways are responsible for the cough reflex, which results in an expulsive cough in response to airway irritation [156]. Cough consists of an inspiration followed by expiration against a closed glottis, with a resultant rise in intrathoracic pressure. On opening the glottis, gas flow is accelerated to a high velocity in the airways with consequent expulsion of mucus and the offending irritant [157].

Figure 2.44 summarizes the factors that operate to determine the level of pulmonary ventilation.

## **Defences of the respiratory tract**

### **Upper respiratory tract**

Each day 10000–20000 L of air, which may vary in temperature, humidity and content of particulate matter and noxious gases, pass into the respiratory tract and are subjected to considerable processing by the upper respiratory tract before entering the lungs. The nose is the first line of

**Fig. 2.44** Synthesis of factors influencing and controlling pulmonary ventilation.

defence in the respiratory tract and has a number of important functions.

#### Air conduction

Adults preferentially breathe through the nose unless there is obstruction, e.g. nasal polyps or mucosal oedema; in infants nasal breathing is compulsory except when crying [158]. During quiet breathing the resistance of the nasal passages (most of which resides in the anterior 2–3 cm of the nose [159]) is approximately 50% of the entire respiratory tract resistance to airflow, while during mouth breathing the upper respiratory tract constitutes only 20% of the total respiratory tract resistance [159]. With each inspiration some air from the paranasal sinuses joins the nasal airstream and the reverse occurs on expiration [160].

#### Defence

There is a high impaction rate of particles greater than  $5\mu\text{m}$  in size, particularly in the anterior part of the nose and in the nasopharynx [161]; very small particles ( $<0.01\mu\text{m}$ ) also settle out by diffusion in the nasopharynx [162]. The nasal mucociliary mechanism propels mucus and deposited particles posteriorly to the pharynx where they are disposed of by swallowing. The transit time for the nasal mucociliary escalator in normal subjects varies from 4 to 30 min, with a mean transport time of 5.3 mm/min

(range 0.5–23.6 mm/min) [163] as determined by the saccharin test [164] or transport of radioactive particles [163]. The mucus secreted in the nose may contain specific secretory IgA antibody [165], as well as other non-specific antibacterial substances.

#### Air conditioning

The nasal mucosa operates a countercurrent heating and humidification system to ensure that air reaching the alveoli is saturated with water and close to body temperature, much of the heat and water added on inspiration being recovered on expiration [166]. The large cross-sectional area and narrowness of the nose ensure maximum contact between air and mucosal surfaces, aided by the low linear velocity of air and the mixing effects of turbulence [166]. The extensive mucosal capillary beds and the presence of erectile vessels are presumably of major importance in regulating the amount and water content of surface fluids, these mechanisms being under autonomic control although the reflex arcs are unknown [166]. Over a wide range of temperatures of inspired air, the nasal air conditioning mechanism achieves a temperature of 28–32°C in the nasopharynx that further increases towards body temperature in the bronchial tree [166]. Mouth breathing is less effective at increasing the temperature of inspired air [166].

#### Lower respiratory tract

##### Mucociliary escalator

The mucociliary escalator is the primary pulmonary mechanism for clearing airway surfaces of foreign materials. Each ciliated epithelial cell bears approximately 200 cilia beating about 1000 times per minute (slower in peripheral airways [167]) in the low-viscosity fluid that covers the epithelium. Scanning electron microscopy demonstrates that discrete flakes or droplets, rather than a blanket, of mucus are transported on the low-viscosity layer [168].

Airway secretions consist of a gel of mucus or glycoproteins dispersed in a continuous sol phase [169]. The volume of airway secretions represents a balance between secretion and reabsorption [170] and in normal laryngectomized patients may be as little as 10 mL daily [171]. Secretion may be increased, e.g. in chronic bronchitis or asthma, either reflexly or via the action of mediators such as the leukotrienes and histamine, which are potent secretagogues [172].

Tracheal mucus velocity can be assessed in humans by measuring the linear velocity of radio-opaque Teflon discs insufflated into the trachea through a fiberoptic bronchoscope; values of about 20 mm/min have been recorded in normal humans [173]. Tracheal mucus velocity is

decreased in smokers and patients with chronic bronchitis and asthma. The decrease seen in asthmatic subjects deteriorates further on antigen challenge, an effect reversed by the slow-reacting substance antagonist FPL55712, suggesting that anaphylactically released leukotrienes may be responsible [174].

The importance of this air-conditioning mechanism is emphasized by the frequent complications seen with endotracheal intubation or tracheostomy if the inspired air is not adequately humidified. Drying of the respiratory mucosa compromises mucociliary transport and predisposes to infection. Nevertheless, the tracheobronchial mucosa is capable of adaptation to a situation in which the warming and humidifying functions of the nose are absent. Patients with total laryngectomy breathe directly in and out of the trachea, and although there is an initial period of adjustment there appears to be little final inconvenience [175].

### Cough reflex

Cough may be consciously or reflexly induced. The reflex is due to stimulation of receptors in the epipharynx, larynx or large airways and is conducted in myelinated fibres [156]. The cough reflex exists as both a protective and a clearance mechanism for disposing of excessive secretions from the airways. Coughing starts with a brief inspiration of air larger than tidal volume followed by glottic closure for about 0.2s, which allows pressure to build up in the abdominal, pleural and alveolar spaces to about 6.6–13.3kPa (50–100mmHg) by an expiratory effort. Active opening of the glottis [157] is followed by accelerating expiratory flow at the mouth that reaches a peak of as much as 12L/s within 30–50ms [157] and terminates usually 0.5s later with glottic closure. The coughing sequence may be repeated rapidly several times, progressing through the lung volumes to RV and successively collapsing more and more of the intrathoracic airways [176].

### Alveolar macrophages

The alveolar macrophages are the sentinels of the alveoli and the probable explanation for the usual sterility of the alveolar surface [177]. These large (approximately 20µm) cells are found free in the alveolar spaces and are believed to be derived, at least partly, from bone marrow mononuclear phagocyte precursors [178–181] and possibly also from local proliferation [182] within the interstitium [183] with subsequent migration to alveolar spaces.

Alveolar macrophages ingest particulate matter after opsonization with C3b or IgG via the macrophage membrane receptors for C3b and the Fc portion of IgG [184]. Alveolar macrophages also ingest bacteria, fungi and viruses [185,186] and this ingestion is optimal following

opsonization by immunoglobulin or complement [187]. Following ingestion of particulate matter or organisms, alveolar macrophages become activated, as shown by increased O<sub>2</sub> uptake [188], more rapid glucose utilization [185,188], increased superoxide production [188] and release of the macrophage chemotactic factor for neutrophils [189]. Activated macrophages have an increased content of lysosomal enzymes [190] and are better microbial killers, presumably through fusion of phagosomes with the bactericidal enzymes present in lysosomes to form phagolysosomes [191].

Alveolar macrophages comprise the majority (>90%) of the cells obtained by the technique of bronchoalveolar lavage via the fiberoptic bronchoscope [192], greater numbers being obtained from smoker's lungs. The alveolar macrophages of smokers are activated, as evidenced by increased numbers of lysosomes, phagolysosomes, endoplasmic reticulum, ribosomes and Golgi vesicles [193,194], presumably secondary to the injection of the particulate matter of cigarette smoke.

Alveolar macrophages are found in sputum and the majority are probably cleared from the alveoli by migration to, and transport up, the mucociliary system. Some possibly migrate to the interstitium and may be cleared by the lymphatic system [191].

### Immunological defence mechanisms

See Chapter 4.

## Other aspects of pulmonary function

### Pulmonary function during exercise

Exercise stresses both the pulmonary and cardiovascular components of the O<sub>2</sub> transport system and responses to exercise are often used in the evaluation of patients with pulmonary disease, particularly in the elucidation of the symptom of dyspnoea [195–199]. Exercise is usually performed on a treadmill or a bicycle ergometer, with the subject being exposed to progressively increasing workloads (e.g. 100kPa·m/min increments every minute on a bicycle ergometer). In normal young subjects exercise continues until exhaustion, but in patients and those over 40 years old exercise is usually stopped when the heart rate reaches 85% of the maximum predicted for age [200]. In a simple exercise test measurements are made before, and at intervals during, exercise of minute ventilation, respiratory rate and tidal volume, cardiac frequency, O<sub>2</sub> uptake, CO<sub>2</sub> output and an index of oxygenation, which is usually O<sub>2</sub> saturation measured by an ear oximeter [63], although arterial blood samples may also be taken.

With increasing workload, or in metabolic terms O<sub>2</sub> uptake, minute ventilation increases linearly until anaerobic sources begin to contribute to the energy supply at

Fig. 2.45 Relationship in a normal subject of cardiac frequency (CF) and ventilation ( $\dot{V}_E$ ) on oxygen uptake ( $\dot{V}_{O_2}$ ) and of ventilation on tidal volume ( $V_T$ ). (From Cotes [204].)

about 50–60% of maximal  $O_2$  uptake, the anaerobic threshold [201]. Above the anaerobic threshold the lactic acid produced by anaerobic metabolism provides an added drive to breathing and ventilation increases more steeply with increasing work rate or  $O_2$  uptake (Fig. 2.45). Tidal volume increases linearly with  $O_2$  uptake until a maximum value is reached above which further increases in minute ventilation are only possible by increasing respiratory rate [202]. Similarly, heart rate increases linearly with  $O_2$  uptake to a maximum dependent on the subject's age [200] (Fig. 2.45). In normal subjects hypoxaemia does not occur even at strenuous levels of exercise [203].

Normal ranges for the cardiovascular and ventilatory responses to exercise have been defined. Since maximal exercise studies are not desirable in patients, a number of simple indices derived from submaximal exercise studies can be used to describe exercise responses [204]: (i) minute ventilation; (ii) cardiac frequency at specified submaximal  $O_2$  uptake, usually 1.0 or 1.5 L/min; and (iii) tidal volume at a fixed level of minute ventilation, usually 30 L/min.

Patients with respiratory disease alone stop exercising at a heart rate below the maximum predicted for their age, since the factor limiting exercise in both obstructive and restrictive disease is the ventilatory capacity [205,206]. The ventilatory response to exercise is therefore greater than predicted while the cardiac response is normal. Where the heart is also compromised, as in recurrent pulmonary embolism or left heart failure, both ventilatory and cardiac responses to exercise exceed predicted values.

A simple test of exercise capacity is the 12-min walking distance, i.e. the distance walked in 12 min on the flat; the only apparatus required for this test is a clock and a corridor [207]. The test has the advantage that it is based on a universally familiar activity (not everyone cycles) and allows subjects to adjust their pace during the test. In patients with airways obstruction or restrictive lung disease, the 12-min walking distance correlates significantly with the response to a standard questionnaire scaling subjective impressions of exertion and with patients' assessment of their own performance using an  $O_2$  cost diagram [207]. The 12-min walking distance correlates better with FVC than  $FEV_1$  in both obstructive and restrictive disease and correlates well with  $DL_{CO}$  in those with pulmonary infiltration. The measurement of 12-min walking distance has since been applied successfully in assessing the value of bronchodilator therapy in patients with chronic bronchitis and emphysema [208,209]. More recently, it has been found that the 6-min walking distance is as useful an index as the 12-min walking distance [210].

### High-altitude physiology

The main factor determining physiological adaptation to high altitude is hypoxia [211,212]. With decreasing atmospheric pressure, the prevailing partial pressure of  $O_2$  also falls (Fig. 2.46); as a consequence the partial pressures of  $O_2$  in the  $O_2$  cascade also fall (Fig. 2.47). The adaptive physiological changes in native-born high-altitude dwellers (natural acclimatization) are complex and range from changes in ventilatory response, haemoglobin and rates of blood flow to carotid body hyperplasia, altered myocardial metabolism, pulmonary arterial hypertension and changes in the rate of body growth. Although Mt Everest (8848 m) has been climbed without supplemental  $O_2$ , there does appear to be a finite level of altitude above which permanent residence is not possible. Andean humans have survived by natural acclimatization at 4200–4500 m for 10000 years but people wintering in the Himalayas at 5700 m have progressively lost weight despite adequate caloric intake. In addition to the adaptive physiological changes seen at high altitude, pathological conditions due to hypoxia also occur and these principally affect the cardiopulmonary system.

### Ventilatory adaptations

Exposure to high-altitude hypoxia increases minute ventilation and lowers  $P_{ACO_2}$ , an effect reversed by giving  $O_2$ . However, after a few days at high altitude there is a further increase in ventilation that is not abolished by  $O_2$  therapy. The resultant respiratory alkalosis is soon compensated for by renal excretion of bicarbonate. This is associated with an increase in the ventilatory response to inhaled

**Fig. 2.46** Inspired oxygen pressures at various heights above sea level. (From Heath & Williams [211].)

**Fig. 2.47** Mean oxygen pressure gradients from inspired air to mixed venous blood in subjects native to sea level and 4540 m and in climbers at 6700 m. The oxygen cascade at high altitude is much less steep than at sea level. In spite of a much lower inspired  $PO_2$  the final  $PO_2$  achieved in mixed venous blood is not much lower at high altitude than at sea level. (Modified from Heath & Williams [211].)

$CO_2$  [213]. The conventional explanation for the maintained hyperventilation is as follows. Altitude hypoxia causes hyperventilation with a resultant decrease in arterial and CSF  $P_{CO_2}$ . The rise in CSF pH that follows minimizes the initial hyperventilation until CSF pH is restored to normal over 5–10 days by active transport of  $HCO_3^-$  out of the CSF. The hyperventilation is then established and, since CSF  $HCO_3^-$  has fallen, small increases in  $P_{CO_2}$  now produce larger decreases in CSF pH with attendant hyperventilation, i.e. an increased ventilatory response to

inhaled  $CO_2$ . However, measurements of CSF pH during acclimatization and deacclimatization do not fit with the above hypothesis and it would appear that other, as yet unknown, factors may be responsible for ventilatory acclimatization [214,215].

The amount of increase in ventilation and decrease in  $P_{CO_2}$  varies with altitude and with time at a given altitude. Andean Indians and Himalayan Sherpas ventilate less than acclimatized lowlanders. This is probably due to their marked carotid chemoreceptor insensitivity to hypoxia [216,217], which may result from exposure to a low ambient  $PO_2$  in the early years of life [218]. Arterial blood gas measurements, minute ventilation and FVC measured at rest in Operation Everest II, a decompression chamber study [212], are shown in Table 2.3. At 8848 m, the height of Mt Everest,  $P_{aO_2}$  was only 4.0 kPa (30 mmHg) at rest and hyperventilation lowered  $P_{aCO_2}$  to 1.5 kPa (11 mmHg) and raised arterial pH to 7.56. FVC fell with increasing altitude, a phenomenon attributed to increased central blood volume and interstitial oedema.

### Haematological adaptations

Both native-born and long-term residents at altitude develop an absolute polycythaemia associated with an increase in the number of red blood cells and in haemoglobin, resulting in an increased transport capacity for  $O_2$ . The haematocrit appears to correlate best with  $SAO_2$ , which of course is dependent on the ambient  $PO_2$ . The polycythaemia is due to an increase in circulating erythropoietin [219] and takes months to develop fully. In spite of the decreased saturation, a given volume of arterial blood in natives resident at high altitudes contains a greater amount of  $O_2$  than is found in controls at sea level. It has also been shown that the affinity of haemoglobin for  $O_2$  is decreased at high altitude so that the  $O_2$  dissociation curve at a given pH is displaced to the right, thus facilitating the release of  $O_2$  to the tissues. This change in affinity is due to increased production in the red cell of 2,3-DPG, which decreases the  $O_2$  affinity of haemoglobin and moves the  $O_2$  dissociation curve to the right [220].

### Circulatory adaptations

Rapid movement to high altitude results in tachycardia. With acclimatization, both the heart rate and resting cardiac output become normal. For reasons that are unknown the stroke volume and cardiac output are reduced during exercise and this applies to acclimatized residents as well as newcomers [212,221–223].

The natives of high altitudes show a moderate degree of pulmonary hypertension that does not correlate well with age or haematocrit and tends to increase abruptly with exercise or further hypoxia. The hypertension cannot be explained on the basis of increased pulmonary blood

**Table 2.3** Resting measurements at several barometric pressures in Operation Everest II [212].

Barometric pressure (kPa)	Altitude (m)	$P_{aO_2}$ (KPa)	$P_{aCO_2}$ (KPa)	Arterial pH	$\dot{V}_E$ (L/min)	FVC (%)
101 (760)*	0	13.7	4.5	7.43	11	100
57 (429)	4800	6.3	3.3	7.46	15	96
46 (347)	6300	5.2	2.6	7.50	21	92
37.5 (282)	8100	4.6	1.6	7.53	37	87
33.5 (252)	8848	4.0	1.5	7.56	42	86

\*, values in parentheses represent mmHg.  
FVC, forced vital capacity.

volume, although this probably occurs to some degree at altitude, and results partly from increased precapillary vascular resistance due to pulmonary arterial constriction caused by hypoxia.  $O_2$  given for short periods reduces the pulmonary hypertension at altitude but the pulmonary artery pressure never reaches sea-level values. This has been explained by a fixed, high pulmonary vascular resistance due to medial smooth muscle hypertrophy in the pulmonary arterial tree. It seems probable that involution of the smooth muscle of the fetal pulmonary vasculature does not occur at altitude because of hypoxia.

Studies of the elastic configuration of the larger pulmonary arteries have been helpful in elucidating the natural course of high-altitude pulmonary hypertension. At sea level the pulmonary trunk of the newborn contains long, parallel, tightly packed elastic fibres as in the aorta. As age progresses the elastic content of the pulmonary trunk decreases [223]. In high-altitude natives, this regression of elastic fibres in the larger pulmonary arteries does not occur and has been found to persist in subjects born at high altitudes who have subsequently lived for several years at sea level. This is in contrast to the medial muscle hypertrophy, which is known to remit, along with the pulmonary hypertension, after prolonged stay at sea level. The persistent elastic configuration of the pulmonary trunk is thought to represent a property of the elastic material in the vessel wall of the adult rather than being evidence of pulmonary hypertension [223].

The functional significance of the pulmonary hypertension of altitude is not known. It may simply be the consequence of accommodation to hypoxia in fetal life.

### Other adaptive changes

High altitude has an adverse effect on body weight and growth generally in the laboratory animal and in humans [224], although the effect is very much less on the lungs so that TLC in relation to height or body weight is increased [224,225]. The membrane component of the diffusing capacity ( $D_m$ ) is increased in high-altitude natives [226] but overall diffusing capacity does not appear to increase in lowlanders with acclimatization [227].

The carotid bodies of subjects living at high altitude in

the Andes are larger than those living on the Peruvian coast [228]. Experimental studies have shown that this also occurs in animals and is presumably due to chronic hypoxia [229].

Coronary blood flow per time and per unit mass is lower at high altitude than at sea level in spite of the lower  $P_{aO_2}$ , contrasting with the classical view that hypoxia is a potent vasodilator for coronary vessels. The lower coronary flow is not compensated by an increased haematocrit or arterial oxygenation; the  $O_2$  supply to the heart is simply lower. Nevertheless a high degree of adaptation seems to occur since there is no evidence of insufficient oxygenation of the myocardium,  $O_2$  extraction by the heart is normal and there is no indication of anaerobic metabolism in normal subjects living permanently at high altitude [230]. The  $O_2$  consumption of the heart is lower through some sparing mechanism of the heart cells, as yet not fully understood. The myocardium at altitude is therefore more efficient in that it can work effectively with less  $O_2$ . While using the same substrates to create its energy, the heart at high altitude consumes more carbohydrate, particularly lactate, and this may explain in part the increased efficiency. It is an interesting observation that angina pectoris and myocardial infarction are rare at high altitude [230]. Anatomical differences may contribute since it has been shown that high-altitude natives have more abundant coronary channels than those resident at sea level [231].

Cutaneous blood flow decreases at high altitude, the blood being redistributed as a reservoir of  $O_2$  to the other organs of the body.

### Diseases of altitude

Acute mountain sickness [232] is a condition affecting lowlanders 6–90 h after rapid ascent to altitude. It is characterized by lethargy, insomnia, headache, nausea, vomiting and dyspnoea. In severe forms cyanosis, crepitations in the lungs, papilloedema and other signs of cerebral oedema are also features. The cause is not known for certain but fluid retention probably plays an important role and pretreatment with diuretics, especially acetazolamide, has proved an effective preventive measure [233].

Loss of acclimatization to high altitude may occur acutely, giving rise to high-altitude pulmonary oedema, or chronically, causing chronic mountain sickness.

### Clinical applications of pulmonary function testing

The application of pulmonary function testing in specific clinical conditions is discussed in the appropriate chapters in this book. In general terms chest physicians need not consider themselves underequipped if access to standardized [234–238] measurements of PEFR, dynamic lung volumes ( $FEV_1$ , FVC), static lung volumes and  $DLCO$ , arterial blood gas tensions and exercise testing responses are available.

Most diagnoses in respiratory medicine can be made (or strongly suspected) after talking and listening to the patient; the diagnosis may be confirmed by the findings made on physical examination (see Chapter 6). Pulmonary function tests may be used to confirm or establish the diagnosis or, in the case of potentially progressive disease, to establish baseline pulmonary function with a view to future monitoring. Many of the tests outlined earlier in this chapter are described solely to enhance the reader's understanding of how the respiratory system functions; most of them have been used only in research applications. In the clinical situation simple pulmonary function tests may provide an answer to the most commonly asked questions: Does this patient have airways narrowing or obstruction? Does this patient have restrictive lung disease? Why is this patient breathless?

For the assessment of *airways narrowing or obstruction* simple measurements of  $FEV_1$  or FVC (see p. 43) are more than adequate. If asthma is suspected, regular monitoring of PEFR (see p. 45) may reveal significant diurnal variation or association with exercise or occupational exposure. Testing for exercise-induced asthma may be necessary. Measurement of a significantly reduced  $DLCO$  or  $Kco$  suggests emphysema but is unlikely to influence management.

The tradition of separating patients with airways narrowing or obstruction into those with 'reversible' and 'irreversible' airways obstruction on the basis of whether  $FEV_1$  does or does not improve by 10–15% following a bronchodilator should be discarded. Improvement in PEFR or  $FEV_1$  following a bronchodilator, however great or small, is usually an indication that the patient will derive subjective and objective benefit (e.g. improved exercise tolerance, 12-min walking distance, see p. 55)

from such therapy. Large improvements in pulmonary function (>20%) following a bronchodilator suggest a diagnosis of asthma; lesser improvements are more consistent with chronic bronchitis and emphysema with airways obstruction; however, there are no absolute rules in medicine.

Maximal flow–volume curves provide no additional useful information on patients with obstructive airways disease. Their value is in the assessment of central airways narrowing, most commonly due to tumour, where it is unusual for clinical or radiological evidence to be absent at the time of testing.

Although the classical symmetrical reduction in  $FEV_1$  and FVC is likely to be obtained in the patient with *restrictive lung disease*, confirmation of the reduced static lung volumes and diminished  $DLCO$  is essential. Resting oxygenation, measured as either  $PaO_2$  or  $SaO_2$ , should also be assessed. Serial estimations of lung volumes and  $DLCO$  are of value in assessing progression of disease and the response, or lack of it, to therapeutic intervention, for example in pulmonary sarcoidosis or cryptogenic fibrosing alveolitis.

The assessment of patients with *breathlessness* presenting to a chest clinic (see Chapter 6) is usually straightforward; on the basis of the history, examination, chest radiology and simple pulmonary function testing most patients prove to have obstructive or restrictive pulmonary diseases [239]. If asthma has been excluded and the chest radiograph, lung volumes and  $DLCO$  are normal, then most primary pulmonary diseases can be excluded as causes of breathlessness although, occasionally, recurrent pulmonary thromboembolism may present in this way (see Chapter 25).

The presence of a restrictive defect as indicated by reduced static lung volumes in the presence of a normal chest radiograph and  $Kco$  suggests the possibility of an extrapulmonary cause such as respiratory muscle weakness. In such cases, determination of maximum inspiratory and expiratory pressures would be appropriate.

It is sometimes difficult to distinguish cardiac from respiratory causes of exertional dyspnoea, particularly in cigarette smokers who may have combined disease. Progressive exercise testing (see p. 54) with determination of the ventilatory and cardiac responses to exercise may provide helpful pointers to the dominant cause of dyspnoea; often the system at fault is only identified by appropriate therapeutic trials.

Finally, a small minority of patients prove to have hyperventilation or related syndromes; these are dealt with in Chapter 48.

# EPIDEMIOLOGY

ANTHONY SEATON

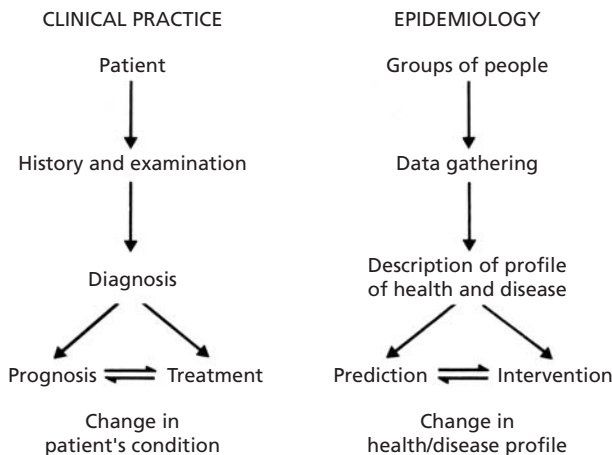

In treating individual patients the clinician has little feel for the overall frequency of disease. Hospital physicians may from time to time become aware of an unusual number of patients with pneumonia or with asthma related to work in a particular factory, but our view of disease is necessarily biased by seeing only a highly selected group of subjects. In clinical practice, therefore, it is usual to spend relatively little time investigating the causes of the diseases one sees, the main concerns being their diagnosis and cure. In order to learn more about the patterns of disease and their causes the physician needs to understand something of epidemiology.

Epidemiology literally means the study of epidemics, a word coined by Hippocrates to describe the concept of the occurrence of disease in patterns, affecting many people at the same times of year (*epi demos*, among the people). As is still the case with much medical research, the study of epidemics has over the centuries been influenced by the fashion of prevailing theories; Galen in the first century AD placed the emphasis on man's constitution, though he recognized that this could be influenced by external factors such as diet or exercise, while Sydenham in the seventeenth century looked upon disease as the body's attempt to expel malign influences, or miasmata, derived from the earth. Such miasmata held sway, with contagion, as suspected causes of disease for almost two centuries after Sydenham, until the gradual appreciation in the nineteenth and twentieth centuries of the importance of microorganisms and pollutants as external, and of genetic factors as constitutional, determinants of disease.

The conflict between apparently rival causes of disease continues, perhaps in a less overt manner, driven by the special interests of research workers. Until quite recently, much research into the causes of disease focused on the pathogenetic mechanisms, for example the immunological, biochemical and molecular reactions occurring when a tissue is injured or as cancer occurs in an organ. Such research clearly has value: in understanding the changes in a cell, it may be possible to modify such changes by treatment or even prevent them by production of a

vaccine. However, the approach has limitations when the ultimate aim is prevention. To take a well-known example, and one that is a classical illustration of the method and purpose of epidemiology, the waves of cholera epidemics in Britain that accompanied the Industrial Revolution were ultimately eliminated by improved hygiene measures derived from the work of John Snow. Snow studied the patterns of these epidemics in London and was able to show greater than fivefold differences in incidence of the disease between populations obtaining their water from different suppliers. He hypothesized that faecal contamination of drinking water was responsible and was subsequently able to test this hypothesis by preventing access to a pump supplying contaminated water to people around the Broad Street area of London and to show that the epidemic then waned. Application of more modern tests to this famous episode might have cast some doubt on the precise causal relationships between removal of the pump handle and decline of the epidemic, but the point was well made: epidemiology has its major application in the prevention of disease.

Since the time of Snow (he published his first work on cholera in 1850, 33 years before *Vibrio* was described by Koch) much has been learnt about the pathogenetic mechanisms of disease. Epidemiology has also spread its wings, and now concerns itself with the overall study of the patterns of health and disease, appropriately in view of the original observations of Hippocrates and Sydenham, rather than confining itself to epidemics of infection. It may be defined as the study of the distribution and determinants of health and disease in groups of people. An important distinction from clinical medicine is thus made: the epidemiologist studies populations, the clinician (*cline*, a bed) studies and treats sick people. However, there is a useful analogy between their activities (Fig. 3.1). The clinician studies a patient, making observations by history-taking and various examinations that properly lead to a diagnosis. This in turn leads to the possibility of both prognosis and treatment, each of which may influence the other. The process is essentially the application of

**Fig. 3.1** Analogy between clinical and epidemiological practice. (Courtesy of Dr Michael Jacobsen.)

deductive logic, a process well known to Sherlock Holmes (whom Sir Arthur Conan Doyle modelled on Dr Benjamin Bell, the Edinburgh surgeon who, among other things, described skin cancer in workers producing paraffin from oil-shale). In this form of reasoning, arguing from the general to the particular, information derived from the general body of medical knowledge is used to draw conclusions about a particular patient. By analogy, but in contrast, the epidemiological process uses inductive logic, arguing from the particular to the general; the epidemiologist studies a group of individuals, gathering data on that group in a systematic way. This allows the description of a profile of health and disease in the group, from which it may be possible to make predictions as to what might happen if certain determinants of health or disease were altered (e.g. if people were prevented from drinking contaminated water). It may also be possible to make recommendations for intervention that could lead to improvements in the health of the group. Thus epidemiology, like clinical medicine, may have as its objective not only description of the pattern of a disease but also its amelioration, but in groups rather than individuals.

## Some principles in planning an epidemiological study

### What is the question?

The stimulus to make observations on groups of people has usually come from observations on individuals by astute clinicians, although recently concern about occupational and environmental pollutants has led increasingly to questions about the safety of substances being asked by non-medical people. The first step in an epidemiological study is to rephrase the often rather ill-defined question in terms that are answerable by the application of this discipline. For example, the clinician may notice a lot of cough

and wheeze in wool-workers and ask if the wool causes asthma. This may easily be answered in a clinical sense by a challenge test in the particular individual, but the epidemiological question requires a different approach. An appropriate investigation may set out to answer the question: What, if any, relationship exists between certain respiratory symptoms and measurements of exposure to wool dust? Or again, the clinician may think there are radiological changes on the chest films of some workers exposed to polyvinylchloride (PVC) dust and ask if PVC exposure causes pneumoconiosis. The epidemiologist might ask: Is there a relationship between exposure to PVC dust and small opacities on the chest radiograph? Note the transformation; the clinician thinks in terms of diseases and their causes, while the epidemiologist thinks in terms of relationships between possible determinants of disease and measurable manifestations of that disease.

Of course, the simple epidemiological question may not be sufficient to satisfy the clinician. To pursue the examples above, one may wish to know about the functional effects of wool dust on the lungs or of radiological changes in workers exposed to PVC. These give rise to additional or subsidiary questions: Is there a relationship between exposure to wool dust and certain measurements of lung function? Do workers with radiological changes have different lung function from other workers without radiological changes? The principle is to write down a short list of simple questions. Much bad epidemiology, in avoiding the discipline of clarity in defining objectives, results in the accumulation of a mass of data from which no useful conclusions can be drawn.

### Keep it simple

In investigating a patient, it is commonplace to perform many complex tests and ask a multitude of questions, analysis of which within the doctor's brain can lead to a diagnosis. The instinct of the clinician embarking upon an epidemiological study is therefore to obtain a lot of information on every individual. However, the complexities of gathering and analysing many pieces of information from hundreds or even thousands of subjects make it desirable that the data obtained are those most directly related to the questions being addressed. Moreover, it is essential that information obtained from groups of people is obtained from each individual in a standardized manner. Every questionnaire administered and every test carried out must be assessed with regard to its repeatability and reliability; clearly the more information obtained, the more scope there is for problems with repeatability and the more care and effort is required to ensure consistency. Another important problem with epidemiological studies is their cost, which is related largely to the salaries of the people carrying out the study. The more complex the study, the greater the cost.

### Define the population

Since the epidemiologist studies groups of people, it is essential that the group to be selected is clearly defined. For example, a carelessly designed study of death from coronary artery disease might mistakenly conclude that the condition is related to coal-mining as the result of investigating the causes of death and occupations of people subjected to autopsy in a mining area such as South Wales. However, examination of the population, in this case those undergoing autopsies, would show that a disproportionately large number of individuals in South Wales are coal-miners, where the law relating to industrial injuries benefit ensures that most miners have autopsies. The flaw in such a study would be a lack of information about the denominator, the autopsy population. In planning an epidemiological study, it is essential to consider first the population at risk. This may be the population of a whole nation or some subdivision by age or geography, the workforce of an industry or a factory, the patients attending a hospital or all those undergoing an autopsy. Each of these groups is selected in some way (even a national population is a mixture of different racial or tribal types) and an awareness of factors influencing this selection bias is important when conclusions are drawn from the study.

The *target population* for a study might be defined as that group whose pattern of health and sickness the investigator wishes to define. This may be too large a group to study, in which case a *study population* might be identified; for example, rather than studying all wool-workers, those employed in a representative selection of factories might be chosen. This may of course introduce some bias, if it happened that particularly dusty or non-dusty factories were chosen, so considerable care needs to be exercised in selecting such a study population. If this group is again too large to examine, a *study sample* might be selected, by a randomized method that can if necessary be stratified to ensure sufficient representation of appropriate age or ethnic groups, ranges of exposure to respiratory hazards, and so on.

### Use an appropriate study design

Perhaps the single most important piece of advice to a clinician planning an epidemiological investigation is to involve a statistician in the design of the study. Most doctors are aware of the frustration at being asked to advise on the care of a patient when delays and errors of management have led to an irretrievable situation. Statisticians might be expected to have similar feelings when asked to analyse the results of a study planned either without a clear concept of the questions to be answered or using a design inappropriate to their solution. Decision on study design stems from clarity in defining the questions,

and several broad types of epidemiological study are discussed below.

In general, a desire to establish the *prevalence rate* of a condition, i.e. the proportion of people in a population at any one time with the disease or symptom of interest, may be satisfied by carrying out a *cross-sectional study*. The *incidence rate* of a condition, i.e. the proportion of people in a population developing a disease or symptom over a defined period, is measured by a *longitudinal (or cohort) study*. A properly controlled cross-sectional study may give clues about the aetiology of disease, for example the finding of a high prevalence of bronchitis in certain polluted towns or of an increased prevalence of asthma in circuit board manufacturers. Such clues may then require specific follow-up studies to test the hypotheses derived from them. Two types of study might be considered: (i) a *case-control study*, in which individuals suffering from the condition of interest are compared with control subjects, either healthy or suffering from unrelated disease; or (ii) a longitudinal study, in which the incidence of the condition in a cohort is measured in relation either to the exposure of individuals in the cohort to the aetiological factor in question or to some planned intervention.

### Standardize the methods

Data gathered in an epidemiological study are obtained from many different people, often by several different observers, and seriously misleading results may be obtained if these data are not gathered in a carefully standardized manner. As a result, bias, which can be systematic or selective, may occur. For example, in a study relating ventilatory function to exposure to respirable quartz dust, failure to standardize the end-point in measurement of vital capacity (possibly also with inadequate calibration of the spirometer) led to a serious underestimate of the subjects' lung function and hence to probable overestimates of the toxic effects of dust [1,2]. In the epidemiology of respiratory disease, the methods most commonly requiring standardization are those used to obtain data by questionnaire, the testing of lung function and chest radiology. These matters are discussed in more detail later. In addition, if documentary data are to be used it is necessary to assure oneself that they have been recorded in a standardized manner and to be aware of possible biases. For example, in mortality studies the data on cause of death are recorded and coded by the Registrars General in the UK in a carefully standardized manner, but depend on the often idiosyncratic diagnoses of individual doctors. Thus in spite of the care taken in coding, there may be regional or temporal differences due to diagnostic fashion. Other matters requiring standardization in respiratory epidemiology might be the recording of certain physical signs, such as lung crepitations or finger clubbing, the taking of an occupational history, or the

estimation of individual and group exposures to airborne dusts.

## Some definitions

### Problems in study design

#### Error

The word 'error' means a mistake in normal usage but has a more specialized meaning in epidemiology: it may be *random*, when it describes the chance divergence from the true value of a result obtained in the study of a population sample because of individual variation and sampling and measurement errors; or it may be *systematic*, when it is known as bias.

#### Bias

Bias is present when the results vary in a systematic manner from the true value; avoidance of bias is probably the major problem in design of an epidemiological study. The two most important sources of bias are in selection of the group for study, *selection bias*, and in making measurements, *measurement bias*. The former occurs when there is a systematic difference between the group selected for study and the population they are taken to represent or the control group. An obvious example would be when people are asked to volunteer for a study, since those willing to take part are likely to be motivated differently and to have different characteristics from those who do not. Similarly, in a random population sample, if a proportion fail to participate because they are feeling too ill or too well, selection bias can occur. More subtly, a cross-sectional study of an industrial population might achieve a high participation rate yet bias occurs because ill people had migrated out of the population or had never been fit enough to be employed, leaving only the most healthy to be studied. This phenomenon is commonly called the *healthy worker effect*. Measurement bias occurs as a consequence of inaccurate measurement, as in the example of spirometry quoted above or when, for example, different chest-film readers have different criteria for the description of radiological opacities. A special sort of measurement bias is called *recall bias*, which occurs particularly in case-control studies where the conditions under which retrospective information is obtained may mean that cases suffering from some disease may recall possible causative factors more easily than can controls without the disease. Some ingenuity in study design is required to avoid falling into such traps.

#### Confounding

Confounding occurs when there are two or more risk factors for an outcome and their effects have not been sep-

arated. For example, in a study of the effects of air pollution on health it has been suggested that prolonged residence in polluted cities is associated with increased risks of cardiopulmonary diseases. Any such study needs to take account of the fact that people resident in such cities are not only exposed to more pollution but, in general, may also be poorer, may be exposed to more toxic fumes at work, may eat a less healthy diet and may smoke more cigarettes than residents of less-polluted cities. These factors, among others such as age and gender distribution, are potential confounders. In a study of the association between exposure and disease a confounder may be defined as a factor associated with both the exposure and the disease being studied. If it is unequally distributed between exposure groups, it may cause any relationships to be wrongly attributed, obscured or altered.

### Descriptions of health/disease profiles

#### Prevalence rate

The prevalence rate is the number of people with the defined condition at one time, or over a short period, expressed as a proportion of the number in the population at risk at that time.

#### Incidence rate

The incidence rate is the number of people developing the condition of interest anew over a defined period expressed as a proportion of those at risk over that period. In this case the denominator is the sum of the lengths of time over which each individual in the study remains free of disease. A somewhat simpler description is the *cumulative incidence rate*, where the denominator is the number of people without the disease at the start of the defined period of study.

#### Mortality rates

The *crude mortality rate* is the number of people dying over a specified period expressed as a proportion of the average number at risk of death over the same period. This index does not take account of such determinants of mortality as the age and social structure of the population, and a more useful means of expressing death rates is by calculating age-, social class- and gender-specific mortality rates. For example, an age-specific rate would be the number of deaths occurring in a defined age group over a given period expressed as a proportion of the total numbers in that age group over that period.

A *proportionate mortality rate* is sometimes used as a simple index of mortality from different diseases. This is the number of people dying from a particular disease over a defined period expressed as a proportion of the total

number of deaths over the same period. It may indicate a disproportionately high risk of death from particular causes in the defined population.

Since most studies of mortality require comparisons between a population thought to be at increased risk and one that might be regarded as being at normal risk, it is usually necessary to compare the study population with a much larger group, typically the national population or even a standard world or European population. At this level there will be systematic differences in age structure, as well as, usually, differences in terms of gender and social status. Such studies require standardization, i.e. expression as the rates that would have been present had the two populations had the same structure. A *standardized mortality rate* (SMR) is the number of deaths in a defined population, adjusted for its age and sex distribution, over a given period expressed as a proportion of that in the standard reference population. Such rates may also be applied to specific diseases, for example SMRs for different types of cancer, and a similar term may also be applied to incidence of disease (SIR), appropriate reference data being available from cancer registries.

### Exposure and dose

The value of studies intended to demonstrate possible causative relationships is greatly enhanced if some measurements of exposure to the putative causative factors are made, since it may then be possible to demonstrate a relationship between exposure and risk of the disease in question. In general it is only possible to make an estimate of *exposure* rather than measure the actual *dose* that individuals in the study have received. Exposure may be expressed with varying degrees of accuracy and may be current, cumulative or historical. The simplest measure of *current exposure* is derived from estimates of, say, dustiness or pollution on a relative scale; however, most studies of workplace exposure now make use of personal or area air sampling over one or several shifts, while in studies of air pollution the recordings made by area samplers are commonly used as a surrogate for exposures of individuals in the population. Such measurements can be used to calculate the approximate dose to the lungs from a knowledge of the size distribution of the airborne particles and the breathing rates of the subjects, although these complex calculations are rarely made. *Cumulative exposure* of individuals is usually calculated as the sum of the products of time spent in particular jobs or areas and the average concentrations of airborne substances in those areas at the relevant times. Such estimates are only possible when measurements of substances have been made systematically in the past or as part of a carefully planned prospective study, but when they have been obtained they have provided powerful data on which to base preventive standards. In some cases it has proved possible to estimate *his-*

*torical exposure* from a study of records of past occupational hygiene monitoring, employment records and reconstruction of past industrial processes. Such estimates have the potential to strengthen conclusions drawn in studies of workplace carcinogens, where the relevant exposure may have occurred many decades previously.

## Epidemiological study designs

A descriptive study is the simplest type of design, intended to delineate the pattern of health and ill-health in a population without attempting to investigate possible causes. Routinely collected data on mortality and as part of the UK General Household Survey are of this type, as are the data gathered in the UK Survey of Work-Related and Occupational Diseases (SWORD) [3]. Such information is valuable because it allows the generation of hypotheses and measures change over time, and may form the basis for further types of epidemiological study [4].

### Ecological study

An ecological study is one in which correlations are sought between patterns of ill-health and other data usually collected for other purposes, such as meteorological conditions, social conditions, and so on. This type of design has been used in many studies of air pollution [5], as well as in the early studies that related changes in asthma mortality to sales of bronchodilator drugs [6] and in those that related mortality from mesothelioma to importation of asbestos [7]. This type of study is particularly useful as a generator of hypotheses, although it may also be used to obtain indirect, but not direct, evidence relating to the testing of a hypothesis.

### Cross-sectional study

A cross-sectional study is designed to measure the prevalence of a condition in a population. It may do this at one particular time, as a census counts the population on one day in the year, or over a defined period. The information obtained in the study may be sufficient to study interrelationships between disease and possible causative factors and thus to provide data of value in prevention. Such studies necessarily have their limitations: they are of little value for studying rare conditions or acute episodes of disease; they are very dependent on good response rates; and they are usually quite expensive, requiring much time in identifying, tracing and examining the sample. Nevertheless, since they are relatively straightforward in design and may also serve as useful starting points for either longitudinal or case-control studies, they are among the most frequently performed types of study.

A cross-sectional study aimed at investigating causes of

disease will include controls. However, the difference between these controls and those in a case-control study should be noted. In the latter, controls are individuals without the disease or symptom in question, while in the former they are subjects unexposed to the putative cause. Many cross-sectional studies use internal controls, i.e. the study population will include people with a broad range of exposures to the factor under investigation, from none to a great deal. Other studies may require separately selected controls, though care should be taken that they are appropriately matched for possible confounding factors such as age, social class, gender and perhaps domestic circumstances.

Cross-sectional studies might be used to determine the prevalence of asthma in a community, the relationship of evidence of respiratory disease to exposure to an industrial pollutant or the influence of work on asthma and of asthma on work. Such examples are discussed in the next section in order to illustrate some of the problems.

### Examples of cross-sectional studies

A physician became convinced that many patients with asthma among the elderly were being misdiagnosed as having chronic bronchitis. In order to make a point, for educational purposes, about the prevalence of asthma in elderly people and also to determine how many patients were undiagnosed, he decided to perform a cross-sectional study [8]. The target population in this case could easily be defined as all people over the age of 70, but to make the project manageable the study population was confined to those living in one town. Access to the register of voters allowed a random sample of 1 in 8 to be taken. The main problem of such studies is deciding upon a definition of the disease in question, in this case asthma. A wide choice is available: it could be an appropriate history, positive answers to certain questions, the demonstration of reversible airflow obstruction or some combination. Whatever is chosen (and it may be decided to have several separate definitions) it is important to ensure that the data are collected in an unbiased and repeatable manner. In this case, several definitions were investigated and it was shown that a history of having suffered from 'doctor-diagnosed asthma' at some time occurred in 6.5% of the old people studied, in 3% of whom it was currently present. Half of those with clinical asthma were unaware that they had the disease. A second problem in such studies is ensuring that the maximum possible number of subjects selected attend the survey. Ideally all should be seen but this is almost never possible. In this example, 86% of the study sample were seen, the others not taking part because they did not want to, were too ill or were unable to cooperate. This level of response was not unexpected in such a survey, even though attempts were made to increase it by carrying out the investigations where neces-

sary in the subjects' homes and in a local community hospital. It could of course lead to bias if a disproportionate number of the non-attenders are suffering from the condition in question and so steps need to be taken to obtain some information on their health; in this case a history of asthma was sought from their general practitioners' records.

A cross-sectional study may be used to investigate hypotheses of causation, either when a disease or abnormality is recognized and one wishes to investigate its relationship to a possible cause or when an environmental pollutant is present and it is desirable to find out if it causes any adverse effects. An example of the former approach occurred when a physician recognized some rather minor nodular shadows on the radiographs of workers producing PVC. Were these related to the exposure? A cross-sectional study was planned to examine the current workforce of the factory together with a sample of ex-workers [9]. The latter were included in order to avoid the bias implicit in studying the current workers, who can be regarded as a survivor population, perhaps of relatively healthy men; this is the so-called healthy worker effect [10]. As part of the study, detailed measurements were made of the workers' current exposures to PVC dust of respirable size and careful occupational histories were recorded from all participants. These allowed estimates to be made of lifetime exposures to the dust. As mentioned in the section on case-control studies, steps had to be taken to have the radiographs read in a standard manner and a panel of three doctors carried this out using International Labour Office (ILO) standard films for comparison (see p. 78). One of the three readers detected a relationship between dust exposure and the presence of small rounded opacities, at category 0/1 (Fig. 3.2). Other investigations in this study led to the description of a relationship between dust exposure and decline in ventilatory capacity, having allowed for the effects of age and cigarettes, and between age and prevalence of irregular opacities (Fig. 3.3). The value of such a study is that it gives quantitative information on the relationships between dust exposure and harmful effects that can be used by the industry in setting preventive dust standards.

Conversely, doctors are frequently asked whether something causes disease. For example, does work with wool cause respiratory disease? If the question is a general one, it may be desirable to keep an open mind about the type of effect and study the relationships between dust exposure across a broad range of the industry and symptoms as recorded by questionnaire. A study to investigate this problem selected some 20 factories, ranging from some employing 200 people to others employing a handful [11,12]. The factories were chosen to represent a cross-section of the processes and of the levels of dustiness found in the industry. Thus the target population was wool-workers, the study population was those workers in

**Fig. 3.2** Prevalence of small rounded opacities (category 0/1 or more) on the chest radiographs of PVC production workers in relation to exposure to respirable dust as recorded by three readers (+; black circle; x) independently. One reader found a relationship between prevalence of opacities and exposure. (From Soutar *et al.* [9].)

**Fig. 3.3** Prevalence of small irregular opacities (category 0/1 or more) on the chest radiographs of PVC workers in relation to their age as recorded by three readers independently. All found an increase in prevalence with age. (From Soutar *et al.* [9].)

the chosen factories and, in this case, it was decided to study as far as possible all such workers, though for practical reasons ex-workers were not included. A questionnaire was designed (see later) to include a broad range of possible symptomatic responses to wool-dust exposure; in this investigation, a substantial minority of the workers

**Fig. 3.4** Estimates with 95% confidence limits of relative risk of (a) wheeze and (b) rhinitis, as recorded by questionnaire, in relation to measured current exposures to dust in woollen mills [11].

studied were not fluent in English so the questionnaire was translated into Urdu, their first language. Tests of logic and reproducibility of the questionnaire in the two languages were carried out before its use in the study. The data were analysed in terms of the relationships between individual symptoms (and groups of symptoms) and current dust exposure and exposure-response relationships were demonstrated with cough, wheeze and rhinitis (Fig. 3.4). Again, the results of this sort of study can be used in debate that leads to the setting of preventive dust standards.

A final example of a cross-sectional study might be to investigate the prevalence of a common disease in relation to one particular cause, for example how much asthma is occupational in aetiology. The same sort of study could be used also to assess the effects of having the disease asthma on employability. Such a study might

sample the population of a town or, better, an area including both town and country with a wide range of industries, and obtain information on symptoms and work by questionnaire.

### Case-control study

A case-control or retrospective study is designed to compare two groups of individuals, one with a particular condition and the other without, with a view to determining whether or not a suspected aetiological factor or response to the disease process is present to excess in the group of cases. For example, the investigator may wish to know whether a particular type of work is important in the aetiology of lung cancer, whether the risks of developing lung cancer are modified by changes in smoking habits or whether subjects with pneumoconiosis have worse lung function than those without. These three examples are used to illustrate some of the problems associated with case-control studies, but to begin with a number of general points about such studies are made.

Firstly, as always, the target population must be defined and the cases *and* controls drawn from this or from the study population derived from it, in order to estimate the exposure to the suspected hazard in the unaffected population. For example, in a study of patients derived from a hospital clinic it is important that the controls are derived from the same referral areas. Secondly, it is important to avoid any other bias in selecting the controls, particularly in relation to exposure status. Thirdly, data gathered for investigation of differences between the groups must be obtained in an identical manner from both cases and controls, preferably by someone who is unaware of which group the individuals are in. Such studies are relatively cheap and easy to design and analyse, and are particularly useful for the investigation of possible causative factors in rare diseases. The end-point of a case-control study is the calculation of an *odds ratio*, i.e. the risk of exposure (or other factor studied, such as physiological consequence of the disease) in the cases as a ratio of that in the controls.

### Examples of case-control studies

If the investigator wished to study the relationship between, say, work in the oil-shale industry and lung cancer [13], one approach might be to contrast the occupational histories of all patients presenting with that disease over a defined period with those of patients presenting in the same area or hospital group with other diseases over the same period. Two problems immediately become apparent: first, who should be chosen as controls and, secondly, what numbers of cases need to be studied to give a reasonable chance of finding an effect of shale work (if one exists). The choice of controls is always problematical. Important confounding factors need to be considered;

lung cancer is a disease of older people and of cigarette smokers and so the control group should as far as possible be matched for age and smoking habits. Equally, it should not be chosen from people whose disease might also have been influenced by work in the shale industry, so should not be confined to patients presenting with bronchitis. An appropriate choice of control population might be patients presenting with cardiac disease, or all patients presenting without respiratory disease, in the same hospital and over the same period, if the referral pattern of the controls were similar to that of the cases. Alternatively, controls might be selected from the electoral register or from general practice lists. The control group may then be sampled from one of these populations according to matching criteria defined beforehand.

The second problem, the number of subjects needed, can be examined statistically [14]. It is intuitively obvious that the target population must contain a sufficient proportion of men who worked in the shale industry. The chances of finding an effect will therefore depend on that proportion, on the strength (or weakness) of the effect of shale work in causing lung cancer, and on the time lapse between work in the industry and the time of the study. Given an appropriate interval for cancer to develop, the ability of a study to detect an effect can be summarized as its statistical power and illustrated graphically (Fig. 3.5).

**Fig. 3.5** Estimates of power of a study of 212 subjects with lung cancer and 221 controls to detect an increased relative risk of work in the shale industry. In the study in question, approximately 20% of the study population had some exposure to work in that industry, giving a 90% chance of detecting a doubled risk of lung cancer [13].

The statistical power of a study is defined as the probability of rejecting the null hypothesis when it is wrong. It is particularly dependent upon the size of the population studied, and calculations of the power of detecting differences at different levels of statistical probability should be made before starting any epidemiological study.

Similar methods on a grander scale have been used to study the effects of modifying smoking habits on the risks of developing lung cancer [15]. Cases were defined as patients presenting with lung cancer, proved histologically, at seven groups of European hospitals. Controls were sampled from other patients presenting at the same hospitals with diseases unrelated to smoking, two controls being chosen for each case. Detailed smoking histories were obtained in an unbiased manner from all participants and analyses were confined to those who had smoked at some time. Recruitment of large numbers of subjects allowed detailed examination of the relative risks of developing lung cancer after smoking for different periods and after having given up or reduced for different periods. The information obtained is thus clearly useful in coming to decisions about advising smokers on changing their habits; the risks were related to length of smoking habit, number of cigarettes smoked and, inversely, to duration since stopping. In general, heavy smokers with a prolonged habit have to wait much longer for appreciable reduction in risk than do lighter smokers with a shorter habit.

A third example, more familiar to most respiratory physicians, is the use of case-control methods to determine the functional effects of disease. To return to shale workers, the question arose as to whether shale pneumoconiosis was associated with abnormalities of lung function [16]. Men with pneumoconiosis were to be compared with men without the condition. Again, several potential problems needed to be resolved. How should pneumoconiosis be defined? Who should be used as controls? The satisfactory resolution of these problems has an important influence on the results and their interpretation. In the study referred to, it was decided to define pneumoconiosis in terms of a majority reading of the radiographs by a panel of readers and to select subjects as cases who had readings above a certain ILO category. The controls were, of course, to be selected from the same defined population of shale workers, were to have radiographs agreed as not showing pneumoconiosis, and were to be matched as far as possible on age distribution and occupational histories. This latter decision was made in an attempt to isolate the effects on lung function of the pathological changes of pneumoconiosis from those of exposure to dust and fumes; in other words, abnormal lung function could be due to the disease or could be a separate effect of the factors that caused the disease. The results of the study showed that men with pneumoconiosis had worse lung function than men without, although in the absence of

detailed information on exposures to shale dust and fumes it was not possible to exclude the possibility that this difference was due to their exposures rather than to the pathological process.

These three examples should illustrate the versatility, value and relative simplicity of the case-control approach. Modern statistical techniques are able to take account of imperfect matching and multiple confounding factors, and much valuable information can be obtained in a relatively straightforward way.

### Longitudinal study

A longitudinal, or cohort, study is designed to measure the incidence of a condition in a population. It therefore has defined starting and finishing points. It may also be used to study the progression of a condition over time. Either of these applications might include measurement of suspected causative factors to relate to the measured responses. Such studies are of necessity complex, time-consuming and expensive, but in return give the most complete information that can be obtained by epidemiology. Among the examples of longitudinal studies most familiar to chest physicians are those carried out to measure the respiratory symptoms and ventilatory function in a group of London engineering and office workers in relation to their smoking habits [17] and those performed to study the mortality patterns of British doctors, also in relation to their smoking habits [18] (Fig. 3.6). Other well-known studies include those intended to follow cohorts of children through periods of their lives in order to elucidate factors important in the development of chronic airflow obstruction [19,20] and those intended to demonstrate relationships between coal-dust exposure and health [21,22].

From what has been said before, some problems of longitudinal studies will be apparent: selection of the cohort, ensuring maximum attendance at survey and ensuring complete follow-up. In particular, there are difficulties in keeping track of participants in a prolonged study that requires their regular attendance for survey, and such drop-out rates may have an important influence on the results. This is less of a problem in mortality studies, where the end-point to be measured, death, requires only ascertainment at a central registry. Nevertheless, keeping full information on the whereabouts of a mortality study population and determining the vital status of all individuals at the chosen end-point of the study have their problems.

### Examples of longitudinal studies

Three applications of longitudinal studies are illustrated: measuring mortality, measuring decline in lung function and measuring the incidence of disease.

**Fig. 3.6** Standardized death rates from lung cancer for cigarette smokers, ex-smokers for various periods, and non-smokers. (Based on Doll & Hill [18].)

### Mortality studies

In principle, measurement of mortality is relatively simple. A cohort is identified (this is usually done retrospectively by using records or census information applying to some time in the past) and followed forwards in time until a proportion has died. The causes of death are obtained from death certificates. The results may be expressed quite simply as the crude mortality rate (numbers dead divided by number in the cohort), either for the whole period of the study or on an annual basis. Use of data on cause of death allows calculation of crude cause-specific mortality rates, and these expressed as a fraction of all deaths give a proportional mortality ratio. However, this sort of information is of relatively little use, as death rates are clearly influenced by many factors that may be present in the cohort and that may cause it to differ from other populations. More useful information requires some form of standardization, particularly for the age structure of the cohort in relation to the age structure of a comparison group, for example adjusting for a disproportionately large number of older subjects who might therefore have been expected to die sooner than younger ones.

To pursue the example mentioned previously of shale workers, it was suggested on the basis of clinical observations that this group of men might be at increased risk of death from cancer [23]. It proved possible to identify a cohort consisting of all men registered in the shale indus-

**Table 3.1** Estimated risks of death of shale workers from various causes relative to those of the general population of Scotland.

Cause	Relative risk	No. of deaths
All deaths	1.00 (0.95–1.07)	1066
Cancers		
Stomach	0.92 (0.60–1.41)	21
Colon	0.58 (0.31–1.07)	10
Rectum	1.16 (0.66–2.04)	12
Lung	0.86 (0.70–1.07)	84
Skin	4.83 (2.18–10.94)	6
Kidney	1.00 (0.37–2.66)	4
Bladder	0.84 (0.42–1.67)	8
Lymphatic	0.88 (0.47–1.63)	10
Circulatory disease	1.05 (0.97–1.13)	610
Ischaemic heart disease	1.00 (0.90–1.12)	352
Bronchitis/emphysema	1.02 (0.80–1.31)	63

Numbers in parentheses represent 95% confidence intervals.

try's provident fund between 1950 and 1960. Fortunately the fund records provided information on the workers' occupations in the industry, so it was possible to investigate mortality in relation to different jobs [13]. Tracing of vital status by local searches and enquiry of appropriate records allowed identification of over 96% of the cohort. The workers were all male and from Scotland and it was thought appropriate that their mortality rates should be compared with those of all Scottish males and with those of all males from the same region of Scotland. Standardized for age, these comparisons give rise to a figure for each cause of death that relates the observed risks of death among members of the shale cohort to those of the reference population, the relative hazard or (multiplied by 100) the SMR (Table 3.1). Such calculations, although giving one figure for each cause, need to be qualified by a statement which describes the statistical confidence that the mortality of the cohort does or does not differ from that of the reference population. This is conventionally done by describing the 95% confidence intervals, i.e. the range of SMRs within which there is a 95% likelihood that the true, but unknown, ratio really lies. Table 3.1 shows that although the SMR for death from carcinoma of the rectum was 116%, this could have been as low as 66% or as high as 204%; in other words, an increased risk could not be demonstrated with 95% confidence. It can be seen that only death from skin cancer appeared to be a special risk for workers in this industry.

In the same study, further analyses allowed examination of the effects of different occupations within the cohort on mortality from different causes but were unable to demonstrate any clear-cut relationships. In contrast, in a study of coal-miners, where the actual exposures of the individuals in the cohort to coal dust had been measured

prospectively, it had been possible to demonstrate clear-cut relationships between dust exposure and mortality from respiratory diseases [22]. Clearly the value of a longitudinal study is greatly enhanced if it includes systematic measurement of factors, such as cigarette smoking or dust exposure, that might be important determinants of fatal disease.

### *Decline in lung function*

As stated before, all epidemiological studies require rigorous standardization of methods. Particular problems arise with longitudinal studies where different investigators may be used at different times, and measures to ensure quality control are essential. These and other important methodological problems are discussed in the account of a study of respiratory health in London workers [17]. The interested reader is recommended to consult this book.

Another study has addressed the problem of decline in ventilatory function of coal-miners in relation to various possible determinants including dust exposure. This research included prospective measurements of dust exposure and 4–5-yearly measurement of ventilatory capacity in a large cohort of coal-miners [21]. In addition, respiratory symptoms and smoking habits were recorded by questionnaire and chest radiographs were taken. One analysis investigated decline in forced expiratory volume in 1 s ( $FEV_1$ ) over an 11-year period in a subgroup of the cohort and was able to relate decline to age, smoking habits and dust exposure [24] (Fig. 3.7). An important feature of this study was the loss of men from the original cohort in the course of the 11 years; the possible effects of this loss on the results were discussed in the paper but were nevertheless the subject of some lively correspondence in the journal subsequently, illustrating the uncer-

tainties surrounding conclusions from epidemiological studies [25–30].

### *Incidence of disease*

A cross-sectional study, as discussed above, may allow useful conclusions to be drawn about relationships between provoking factors and disease. However, these conclusions may be much affected by the absence of people who may, by dying or falling ill and thus leaving the workforce, have shown the most marked effects. Or, possibly, fitter people may have been best able to leave for better or healthier jobs. Longitudinal study of a cohort of subjects may overcome this problem, but only if a very high proportion are able to be kept in view. Mortality studies, discussed above, use death as their end-point. Morbidity studies require regular examination of the cohort to detect the disease of interest, which must therefore be one that, having occurred, persists. Clarity of definition of the end-point is essential, and this may not be easy as disease usually occurs not as a sudden event but as a gradual change on a continuum from health. For example, it might be desirable to measure (to pursue the coal-mining theme) the incidence of progressive massive fibrosis in miners. Such information would of course be of little practical value in the absence of information on the dust exposures causing the condition. Any such study should therefore ideally measure dust exposures of the individuals prospectively from the day they enter the industry and take regular radiographs in order to detect the disease at the earliest stage. Such a study would be impracticable, although close approximations have been made. The best known of these, from which several of these examples have been taken, is the British coal industry's pneumoconiosis research, in which a sample of some

Fig. 3.7 Estimates of decline in forced expiratory volume in 1 s ( $FEV_1$ ) over an 11-year period in a population of coal-miners in relation to time, smoking habit and dust exposure. (Derived from Love & Miller [24].)

50 000 miners was followed prospectively by questionnaire, spirometry and chest radiography every 5 years [21]. Prospective measurements of exposure to respirable dust were made on the basis of sampling for occupational groups and detailed occupational histories, and were added to careful estimates of past exposure. Because of the complexities inherent in analysis of such a large study, various subsamples have been examined and the risks of progressive massive fibrosis in these groups estimated. One such analysis concerned the risks after leaving the industry and showed, *inter alia*, that over an 11-year period after leaving a miner with category 1 simple pneumoconiosis has a 17% chance of developing massive fibrosis [31] (Table 3.2). More importantly, another study has shown the risks of massive fibrosis in currently working men in relation to dust exposure, information that can be used for preventive standard setting [32] (Fig. 3.8). All these conclusions are dependent on the definition of the end-point. In the former study this was a majority reading of massive fibrosis by a panel of five readers, of whom one was medically qualified. Subsequent review of the films by an experienced physician resulted in agreement in 82% of cases. In the latter study, it was a clinical reading of massive fibrosis by one or more experienced physicians. Further discussion of the effects of multiple

**Fig. 3.8** Estimated risks of developing massive fibrosis in coal-miners exposed for 35 years to dusts of differing carbon contents in relation to average level of dust exposure.

Category of pneumoconiosis prior to leaving industry (ILO)	0	1	2	3	All
Incidence over 11 years (%)	3.7	16.8	20.5	47.1	8.2

ILO, International Labour Office.

readings can be found in a third paper on this subject, in which readings were made by a large panel of specialized physicians [33].

An application of longitudinal studies of topical interest might be to assess the incidence of asthma in a workforce. The two difficulties mentioned above, of definition and of drop-out, are particular problems here. Asthma is hard to define epidemiologically, whether in terms of symptoms or in terms of variability in function, and sufferers from work-induced asthma have an understandable tendency to seek employment elsewhere. Judging from cross-sectional studies in which attempts have been made to follow up ex-workers, this loss of affected individuals may be a substantial one in, for example, industries involving exposure to colophony [34,35].

In designing a longitudinal study of occupational asthma a definition would first have to be agreed; this might be achieved by questionnaire supplemented by readings of peak flow rate. The population would have to be identified and their (and management's) agreement sought. An initial survey would establish the prevalence of current asthma and all such individuals would of course be excluded from the prospective study of incidence. However, they might be followed up in order to study the influence of change of job on their disease. An appropriate follow-up interval would then be determined and special efforts made to ensure that leavers would be included in subsequent surveys. Steps would have to be taken to avoid possible bias due, for example, to knowledge among the workforce of the possibility of compensation claims. Finally, environmental monitoring would need to be carried out in such a way that incidence could be related ultimately to exposure, and to take account of changes in levels resulting from improved industrial hygiene. Two such studies along these lines have reported relationships between exposure to flour and laboratory rat allergen and the risks of developing respiratory sensitization [36,37].

### Mixed studies

The main types of epidemiological study can of course be combined, and this often proves an attractive and efficient method of studying a problem. For example, both descriptive and cross-sectional studies may provide useful starting points for a prospective study of mortality or disease incidence, and may also be used as methods of identifying

**Table 3.2** Incidence of massive fibrosis per 100 men over an 11-year period in ex-miners by category of pneumoconiosis at time of leaving the industry.

subjects for a case-control study. The latter design is often described as a 'nested' case-control study.

### Experimental studies

All physicians are familiar with the randomized controlled trial, introduced in the early investigations of the treatment of tuberculosis and now the foundation of 'evidence-based medicine'. This is a particular application of epidemiology in which patients are allocated randomly to alternative interventions, usually with pharmaceuticals, in order to compare different clinical responses and rates of side-effects. In such studies, ethical aspects are of paramount importance to the design. Experimental studies may be very large, as in some of the multicentre investigations of new cardiac drugs, and may be applied to the investigation of other interventions such as vaccination and dietary alteration in field and community studies.

### Standardized methods in the epidemiology of respiratory disease

The tools of epidemiology are standardized methods for examining individuals in the populations being studied. Such methods must be capable of producing the same results when applied to the same individual on different occasions both by the same observer and by different observers, i.e. intraobserver and interobserver error must be small, the results of the examination being said to be repeatable. In addition, the method should have been validated or be capable of validation, in that studies should show that the results of using it relate to some standard measurements of illness or its determinants. For example, a questionnaire on dyspnoea might be validated by reference to measurements of exercise tolerance or lung function and a questionnaire on cough might be validated by direct observation of the coughing habits or sputum production of individuals. More commonly in epidemiology, however, validation is made indirectly. For example, a method of reading radiographs could be validated by showing that category of change relates to measurements of exposure to dust; or a questionnaire on symptoms could be validated by showing that severity of the symptoms relates to smoking habits. Finally, in terms of validation, a useful test for detecting illness is both sensitive and specific, i.e. it detects most cases of the illness (producing few false-negative results) and it picks out predominantly individuals with the condition (making few false-positive diagnoses). Table 3.3 illustrates some commonly used terms.

In addition to the above criteria, which of course apply equally to clinical, epidemiological or screening methods, three others are important in epidemiology: the method should be acceptable to the subjects and therefore not provoke a reduced rate of participation; it should be

**Table 3.3** Validation of a test.

Study method	Reference test result		Totals
	Positive	Negative	
Positive	True positives (a)	False positives (b)	Positives (a+b)
Negative	False negatives (c)	True negatives (d)	Negatives (c+d)
Totals	True positives (a+c)	True negatives (b+d)	

Sensitivity of study method =  $a / (a + c)$   
 Specificity of study method =  $d / (b + d)$   
 Systematic error (ratio of study method positives to 'true' positives) =  $(a + b) / (a + c)$   
 Predictive value (proportion of study method positives that are 'truly' positive) =  $a / (a + b)$

simple, so that the operator and the subject are both able to perform it; and it should be objective and not subject to bias as a result of poor cooperation or knowledge of expected result.

### Questionnaires

Each individual question in a questionnaire can be subjected to the above criteria and used in epidemiological analyses. In designing a questionnaire, the principles outlined at the start of this chapter should be taken into account, and in general it is wise to use a tested, reproducible and validated questionnaire rather than start from scratch. Fortunately the British Medical Research Council has published both short and longer versions of one such questionnaire for the study of respiratory symptoms [38,39] and this forms the basis of most subsequent questionnaires, two of which are those published by the European Coal and Steel Community and the American Thoracic Society [40,41]. For international comparisons, validated translations of the questionnaire are necessary and here the European one may be of particular value.

These questionnaires deal with the common symptoms of cough, sputum production, breathlessness and wheeze, and enquire also about previous respiratory health. They include questions on smoking that allow estimates to be made of pack-year cigarette use. They may be complemented by questions on occupational history; these should obtain a chronological account of all jobs done since leaving school and are best taken by someone familiar with the occupational environments in question. In any study of occupational factors in disease, investigation of that environment by an occupational hygienist and classification of the various jobs in terms of suspected respiratory hazard is an essential preliminary.

The above-mentioned questionnaires are excellent tools for the study of what might be termed irritative

bronchopulmonary reactions, such as chronic bronchitis, industrial fibroses and so on, and were not specifically designed to study hypersensitivity reactions, such as asthma and allergic alveolitis. Specific questions therefore need to be added for these purposes. In studying asthma, several investigators have found that the best question is a direct enquiry about whether the subject has, or has had, asthma. The difficulty stems from the fact that clinical asthma is the end of a continuum of bronchial reactivity that manifests itself in a number of different ways. Logically, therefore, it would seem sensible in investigating 'asthma' epidemiologically to study the presence of various complexes of individual symptoms in relation to either some standard, such as measurements of variability of function or histamine responsiveness [42,43], or to some suspected determinant, such as exposure to dust or fume [44]. One such questionnaire has been devised to study the relationships between respiratory symptoms and response to dust in the wool industry [11]. Although rather longer than it might ideally be (it takes about 15 min to administer), it has been shown to be reproducible, valid in terms of demonstrating relationships between symptoms and dust exposures, and to perform equally well in translation into Urdu. It includes questions designed to quantify variability of symptoms, aimed at measuring the most important feature of clinical asthma, and intended to assess relationships between symptoms and work. These latter questions have been designed in a way to minimize bias, by avoiding the suggestion that symptoms and work may be related (e.g. Is your cough worse at work?). Another questionnaire found useful by the author was designed to assess the variability of airflow limitation by asking questions about exercise tolerance when the subject's chest is at its best and worst [45], deriving a score that related to serial measurements of peak flow rate.

The advantages of a standardized questionnaire are that results obtained with it can be compared directly between, for example, different countries, areas or industries. This presupposes that the questionnaire is administered in a standardized manner, without prompting or helping the subject other than by repeating the question. From this it follows that the questions must be designed in such a way as to make it likely that the subjects will be able to answer with a simple 'yes', 'no' or a number. In embarking on a survey, the clerks administering the questionnaire must be carefully trained; instructions for the use of standard questionnaires have been published by the Medical Research Council, the European Coal and Steel Community and the American Thoracic Society [39–41]. Useful information may be obtained relatively inexpensively by means of self-administered questionnaires. These of necessity should be extremely simple to understand and complete. Their length is inversely related to the likelihood that they will be returned. The use of postal questionnaires always requires some form of back-up; it is usual to send a second

request to those who do not return the questionnaire first time and then, if necessary, to follow this up with a visit by the researcher. With appropriate checks on identity of responder, it is also possible to carry out questionnaire surveys by telephone, although here any bias arising from factors such as relative wealth associated with possession of the telephone need to be taken into account.

### Physical examination

There is no reason why elements of physical examination should not be used in epidemiological studies of lung disease, as the recording of blood pressure has been used in cardiovascular epidemiology. However, relatively little use has been made of this, perhaps reflecting the lack of value of most signs as indicators of disease. Repetitive crackles have been used in studies of asbestosis [46] and some studies of crackles and wheezes have been carried out in PVC workers [47]. The clinical measurement of forced expiratory time has been assessed in terms of its reproducibility and validity [48]. Any use of physical examination in epidemiology requires careful standardization of methodology together with some preliminary assessment of its reliability.

### Lung function testing

In contrast to physical examination, lung function testing has formed an important part of most epidemiological studies of respiratory disease. Again, the criteria of simplicity, acceptability, reproducibility, objectivity, specificity and sensitivity need to be taken into account when choosing a test. It is important to realize that these criteria may be met to different degrees in field studies and in the laboratory. Most studies have used simple measurements of spirometry (FEV<sub>1</sub> and forced vital capacity) as these are particularly robust tests. However, studies of diseases causing fibrosis, such as allergic alveolitis or asbestosis, may require measurements of lung volumes, diffusing capacity or even exercise testing. In the investigation of early evidence of bronchial disease it might be desirable to use tests of 'small airways' function. The reproducibility of various tests of lung function in the laboratory and in the field is illustrated in Table 3.4 [49]. This table illustrates, *inter alia*, the unacceptably high variability of the tests of so-called small airways function, i.e. maximal flow at 50% of vital capacity and closing volume. In general, other tests show relatively low variability, at least in the hands of the authors of that paper, though results in the field are usually slightly more variable than those in the laboratory.

A particular problem in epidemiology is the measurement of variability of airflow obstruction in the assessment of asthma. Several methods have been used, of which the simplest in concept is measurement of peak flow rate at frequent intervals over a period of days or

**Table 3.4** Reproducibility of selected lung function tests in the laboratory and in the field. (From Love *et al.* [49].)

Variable		Subject numbers	First test		Second test		Variation between tests

CV, closing volume; FEV<sub>1</sub>, forced expiratory volume in 1 s; FVC, forced vital capacity; TLC, total lung capacity; VC, vital capacity.

weeks. The difficulties of analysing these multiple data have not been completely resolved, particularly as variability is related to the initial level of flow rate; some summary statistic of variation is commonly used. Other methods of studying variability include the use of simple exercise testing, response to bronchodilators and methods of testing bronchial reactivity to inhaled histamine or methacholine [50–52].

In using lung function tests in epidemiology, there is sometimes debate as to whether results should be expressed directly or as a percentage of a value predicted from a regression equation. If the latter method is used (which has the advantage of comparing the results with some external standard), it is important to ensure that the population from which the predictions were derived was an appropriate one. Often, when comparisons between healthy and ill people are being made, there is no need to introduce this complication and the direct results of the tests should be used. In cross-sectional or longitudinal studies, the results from the epidemiological population can be used in multiple regression analyses to develop predicted values for the population in relation to age, height, smoking and so on. If a reference population is required, appropriate equations have been published [53,54]. When using these, it is important to take account of the racial composition of the population, as values differ somewhat, not unexpectedly, in different racial groups [55–57].

### Chest radiography

The chest radiograph has been and remains as important

an epidemiological tool as lung function tests. The taking and reporting of a chest radiograph are relatively complex processes, but use of standardized radiographic technique coupled with the use of standard films for comparison with those under examination have allowed these processes to be widely and effectively applied to epidemiology. These standard techniques and films have been published by the ILO, most recently in the 1980 revision [58]. The booklet accompanying the films describes the methods to be used, which are summarized briefly here.

### ILO classification

The classification is strictly one for epidemiological investigation of the pneumoconioses, although it may be used for other pulmonary fibroses that cause similar appearances. The shadows are categorized as small or large opacities. The former are subdivided into rounded or irregular opacities, each being subclassified on the basis of predominant size. Rounded shadows are denoted p, q and r, while irregular ones are called s, i or u (Table 3.5). Profusion is assessed, again by comparison with standard films on a broad scale of 0 (least) to 3 (most). The broad categories are subdivided (Table 3.6) on the basis of whether the film is thought to be, say, category 1 but category 0 was seriously considered (1/0), or category 1 but category 2 was considered (1/2), into a 12-point classification. The classification also requires description of the lung zones affected and the presence of large opacities, which are classified as A, B or C in ascending order of size. In addition there are methods for recording size and type of pleural plaques, diffuse thickening and calcification. Symbols are provided for

recording other features, such as tuberculosis, emphysema, bullae, tumours, and so on. Comment is also required on film quality. Thus a complete classification would include film quality, presence, site and category of small shadows, predominant types of small shadows (either one or two), presence and extent of pleural shadows and any other features. If shadows consistent with massive fibrosis are present, they should be staged as A (greater than 1 cm and up to 5 cm in maximum diameter), B (above 5 cm but less than the volume of the equivalent of the right upper zone) or C (greater than B). If multiple lesions greater than 1 cm are present, their maximum diameters are summed.

Use of the ILO classification

A common question asked by the novice reader is: How do I know if the changes are due to pneumoconiosis or some other disease such as tuberculosis? This arises particularly when the reader is responsible for making a clinical decision about the patient as well as producing an epidemiological classification, but also arises as part of the decision as to whether or not to assign a film a pneumoconiosis classification. It is useful to separate the clinical and epidemiological roles clearly, and the author teaches new readers to imagine that they have two hats, one labelled ‘clinician’ and the other ‘epidemiologist’, only one of which may be worn at one time. The following sequence of decisions is suggested.

- 1 Read the film wearing the clinical hat and report any significant abnormality. This diagnosis would normally lead to further clinical investigations by the doctor or a colleague.
- 2 Put on the epidemiologist’s hat and start epidemiological classification by asking if any of the appearances

Table 3.5 International Labour Office classification of small opacities: the predominant types should always be determined by reference to the standard films.

Rounded
p: up to 1.5 mm diameter
q: 1.5–3 mm diameter
r: 3–10 mm diameter
Irregular
s: up to 1.5 mm in width
i: 1.5–3 mm in width
u: 3–10 mm in width

could be due to pneumoconiosis; if so, classify. Note that there is a very wide range of appearances of pneumoconioses and one should err on the side of including doubtful films.

- 3 Record film quality and do not classify if this is very poor.
- 4 Classify acceptable films according to the ILO protocol.
- 5 Make any clinical comments, for example doubts about the pathological nature of the shadows classified, so that these may be taken into account in the analyses.

The reader should sit in a darkened room and use a uniformly bright viewing box with space for at least three films. The film to be classified should be compared with whichever standard film or films is thought to be closest in appearance. It is wise to keep a standard 0/0 film on the viewing box throughout in order to keep in sight what a normal film looks like; this avoids underclassifying films with early changes. Attempts to keep the classification in one’s head result in excessive use of the middle category (1/1, 2/2 or 3/3) and increase interobserver differences [59]. The results should be recorded on standard preprinted forms in the same order as specified by the ILO booklet. In any epidemiological reading exercise, it is important that doctors forget their medical qualification (and with it their natural inclination to *interpret* the shadows) and simply record what they see. Indeed, it is perfectly possible to train non-medical people to read films very adequately for epidemiological purposes [60,61]. Even with careful adherence to the ILO guidelines, there will be differences between different readers. While these can be reduced by special training and feedback of results, they can also be used epidemiologically. For example, some readers may be more sensitive to early changes and may detect relationships between small shadows and age and smoking as well as dust. Other readers may be less sensitive to such changes, but may detect stronger relationships between the shadows and dust exposure. An example of such differences, from a study of the radiographs of shale workers, is given in Table 3.7 [62]. This illustrates the value of independent analyses of the results from each reader separately, rather than (as is often done) the production of some average reading. It can be seen that three of the four readers detected an effect of working in shale mines, though at somewhat different relative risks. All readers detected an effect of age on the prevalence of small opacities (both rounded and irregular were included in this analysis), and in addition two detected an effect of smoking. Interest-

0/–	0/0	0/1	1/0	1/1	1/2	2/1	2/2	2/3	3/2	3/3	3/+
Category 0			Category 1			Category 2			Category 3		

Table 3.6 International Labour Office classification of profusion of small opacities.

**Table 3.7** Analysis of readings of radiographs of shale workers by four separate doctors. Results of multiple regression analysis of relations between readings of 1/0 or more and various possible determinants of those appearances. (From Seaton *et al.* [62].)

Reader	Possible determinant	Relative risk	P
1	Per 10 years in shale mines	1.63	<0.0001
	Per 10 years increase in age	2.16	<0.0003
2	Per 10 years increase in age	1.94	<0.0001
3	Per 10 years increase in age	1.79	<0.0001
	Ex-smoker relative to smoker	0.72	<0.0001
	Non-smoker relative to smoker	0.41	<0.0001
	Per 10 years in shale mines	1.2	<0.01
4	Per 10 years increase in age	1.65	<0.0001
	Ex-smoker relative to smoker	0.77	<0.0004
	Non-smoker relative to smoker	0.39	<0.0004
	Per 10 years in shale mines	1.19	<0.022

ingly, when the analyses were confined to readings of the higher category of 2/1 or greater, only shale mining and age effects were detected.

Epidemiological studies that use only one reader, no matter how eminent, should be treated with considerable suspicion. Indeed, the more distinguished, the less likely is the reader to use standard films and the more likely to interpret rather than record. In reporting studies using the ILO classification, it is useful to record the degree of inter-observer and intraobserver variability in the panel of readers, obtained by recycling a sample of the films among the readers.

An important aspect of epidemiological film reading is the assessment of change in category, either progression or regression. Much has been written of the respective merits of side-by-side comparisons and of independent classifications of individual films from the same subject [63]. Both methods have advantages and disadvantages but either is acceptable epidemiologically so long as an appropriate protocol is followed. In general, more progression will be recorded when films are read side by side and the order of the films is known; this bias should be acknowledged when the study is published.

## Screening for disease

One application of epidemiology is screening for disease, usually in order to detect it at a stage at which intervention could influence its course. This is therefore an adaptation of a prevalence study. The technique has been widely practised by chest physicians, with considerable success, as part of the drive to eliminate tuberculosis; more recently, consideration has been given to population-based screening for lung cancer, while a number of indus-

tries carry out regular screening for occupational diseases such as pneumoconiosis.

Before embarking upon a screening programme, it is important to consider a number of questions related to its value and justification [64].

1 Is the condition important for individuals and the community?

2 Is there effective treatment for the condition?

3 Is the natural history of the condition, particularly its evolution from latent to overt disease, understood?

4 Is there a recognizable latent or early stage?

5 Is there an acceptable and reliable screening test?

6 Are facilities available for further investigation and treatment of people found by screening?

7 Is there an agreed policy on whom to treat?

8 Does early treatment influence the course of the disease favourably?

9 Is the cost of case-finding and management of cases acceptable in relation to the overall cost of healthcare?

10 Do the potential benefits for true positives outweigh the disadvantages of dealing with false positives?

Ideally, the answers to all these questions should be in the affirmative. Two examples may be used to illustrate this: general screening for cystic fibrosis and specific screening of an industrial population for lung cancer. In the first example, with respect to antenatal or early postnatal diagnosis, the answers to questions 1, 3, 4, 7 and 8 are clearly positive. Effective, though not at present curative, treatment is available (question 2) but facilities for providing it are not always readily available (question 6) and the cost of their provision may well not be acceptable in some economies (question 9). The disadvantages that accrue to the parents of individuals in whom false-positive diagnoses have been made can be considerable in terms of producing anxiety and invalidity (question 10), so a very sensitive and specific test is necessary. The use of modern methods of intrauterine diagnosis fulfils these criteria (question 5) [65,66], though the predictive value can only be kept adequately high if the prevalence of the condition in the screened population is high, and this is therefore generally only applied in pregnancies after screening of the parents for heterozygote status. With respect to screening of individuals for carrier status, it is apparent that screening of all pregnant women and their partners has important potential benefits, partly countered by their costs and the anxiety caused in those screened [67,68]. The availability of reliable screening tests for heterozygotes has made this a very widely discussed issue; these matters are considered further in Chapter 30. Prenatal detection of carrier status clearly has ethical and management advantages over detection during pregnancy, although this has important cost implications and may cause problems in terms of causing both anxiety and false reassurance [69,70].

In the case of screening for lung cancer in a workforce with the intention of early detection and surgical cure, the decision may rest on the answers to questions 5 and 10. Sputum cytology may well be an acceptable screening test but its employment on a large scale demands large resources. If the disease is a relatively uncommon one, as lung cancer is in people of working age, and if the incidence is not very greatly increased by the industrial exposure in question, then the predictive value of the test will be relatively low and the problems arising from a relatively high number of false positives (leading to chest radiography, CT scanning, bronchoscopy and possibly thoracotomy) in proportion to the numbers of true positives cured will be disproportionately large. In general, the evidence suggests that population screening for this disease is of little or no benefit in terms of outcome [71]. Care should be exercised in judging papers that investigate this, since it is likely that patients detected during routine periodic screening will have, on average, slower-growing tumours, and the fact that they are detected earlier will mean that they would be expected to survive longer than those detected at a later stage whatever treatment is used.

## Determination of the cause of disease

As stated at the beginning of this chapter, epidemiology may be defined as the study of the distribution and of the determinants of health and disease in groups of people. However, the statistical methods used in epidemiology point to relationships between disease and its determinants rather than to causation of disease. Evidence of association is not necessarily evidence of causation. An investigator who wishes to comment on the cause of a disease should look at all the available evidence in terms of the criteria proposed by Bradford Hill [72].

1 *Strength of the association.* A strong association, one that is highly unlikely to have occurred by chance, suggests a cause-and-effect relationship.

2 *Consistency of the association.* Do all, or most, of the properly conducted studies of this relationship point in the same direction?

3 *Specificity of the association.* Is the disease confined to a particular group exposed to a particular agent?

4 *Relationship in time.* Does the disease follow the exposure after an appropriate time interval?

5 *Biological gradient.* Can the risk of disease be related to exposure to the suspected cause?

6 *Biological plausibility.* Does the relationship make biological sense?

7 *Coherence of the evidence.* Do the observed relationships conflict with what else is known of the natural history and biology of the disease?

8 *Experimental evidence.* Are the observations supported by studies in animals or in the laboratory?

9 *Analogy.* Do the observations accord with other previously described associations in other fields?

These criteria do not all have to be satisfied of course, but each in turn may give further support to a hypothesis of causation. Lung cancer and cigarette smoking, for example, are strongly associated, the risk in smokers being about 10 times that of non-smokers (criterion 1). The association has been shown in a multitude of studies (criterion 2); although the disease is not the only condition of which smokers are at increased risk of dying, the strength of the association is such that the criterion of specificity is satisfied (criterion 3). The temporal relationship between smoking and development of cancer seems appropriate (criterion 4) and a biological gradient has been established (criterion 5). Biological plausibility is strong, in that smoke contains known carcinogens (criterion 6), and the evidence is coherent in that, for example, death rates from cancer have fallen in groups who have reduced their smoking habits (criterion 7). Animal experiments have not been successful in producing experimental evidence in support of the epidemiology (criterion 8) and useful analogies are hardly necessary in the face of such strong evidence. Rather, smoking and lung cancer provides a useful criterion 9 for other associations.

Another extremely strong piece of evidence is that associating mesothelioma and exposure to blue asbestos, in which all the criteria are satisfied. In many other examples, for example the relationships between air pollution, asthma and lung cancer, exposure to mycobacteria and sarcoidosis, and occupational exposure to dusts and emphysema or pulmonary fibrosis, the evidence is less clear-cut and needs to be strengthened before a cause-and-effect relationship can be assumed.

# LUNG DEFENCES AND IMMUNOLOGY

CHRISTOPHER HASLETT

Like the skin, the lung is continuously exposed to the external environment; unlike the skin it is a critically important gas-exchange organ, the membranes of which are delicate and need to be kept moist. Every day the lungs are exposed to more than 7000 L of air and its fine tissues require protection from the daily bombardment of particles, including dust, pollen and pollutants, and the viruses and bacteria that have the potential, respectively, to cause lung injury or to invade the lung and generate life-threatening infections. However, these problems rarely occur because the lung possesses very effective local 'primary' protective mechanisms, which are the focus of this chapter. If an infectious agent is able to penetrate these defences and set up a bridgehead, highly effective and complex 'secondary' responses including the inflammatory and classical immune responses can rapidly be recruited. In the event that an immune or inflammatory response is initiated, the lung also has mechanisms by which it can protect itself from their potentially detrimental local effects. The inflammatory and immune responses themselves are only briefly mentioned; detailed treatment of these processes can be found in Chapters 27 and 33, where their roles in the adult respiratory distress syndrome and asthma are discussed.

The respiratory tract is protected by different mechanisms at its various levels. In general terms, physical mechanisms including cough are particularly important in the upper airways. The lower airways are served by the mucociliary clearance mechanism, and the gas-exchange units (terminal bronchioles and alveoli) are protected by surfactant and cellular defenders, including the patrolling alveolar macrophages. The lung lining fluids (mucus in the upper airway and surfactant in the gas-exchange units) contain a variety of proteins with important properties in host defence against infection and also other proteins that can help protect local healthy tissues against bystander injury in the event that it is necessary for the lung to generate a protective secondary inflammatory or immune response. The lining cells of the lung, especially the epithelial cells, are able to generate many of these pro-

teins themselves. These cells have also evolved important cytoprotective antioxidant and antiproteinase mechanisms, and it is now recognized that, like the resident lung macrophages, they are able to synthesize a wide range of important cytokines and chemokines and thereby play a central role in the initiation of inflammatory and immune responses.

This chapter considers physical defences including cough and mucociliary clearance, surfactant and other protective agents in the lung lining fluids, epithelial and endothelial cytoprotective mechanisms, and the role of alveolar macrophages and other cells in lung defence.

## Physical defences

The nose is the first important contributor to the physical defences of the upper airway. It comprises a stack of fine aerodynamic filters of respiratory epithelium covering the turbinate bones that remove most large particles from the inspired air. The filtering effect is greatly enhanced by fine hairs in the anterior nares and by mucociliary action which, apart from a small area anterior to the inferior turbinates, is directed posteriorly such that trapped particles are swallowed or expectorated. During cough and expectoration the larynx acts as a sphincter, which is an essential protective mechanism for the lower airways during swallowing and vomiting. Larger particles that penetrate the nose and are deposited by impaction or sedimentation in the main airways are trapped by the lining fluids of the trachea and bronchi and cleared by the mucociliary clearance mechanism (also termed the mucociliary escalator); those smaller particles, down to a few nanometers in size, deposited in the acinar part of the lung are dealt with by alveolar macrophages.

## Cough

Cough is both an important reflex mechanism protecting the airways [1] and a common symptom of respiratory disease. The cough reflex can be stimulated by particulate

matter, extremes of air temperature and irritant fumes, as well as by excessive production of mucus itself. A range of inflammatory mediators is also known to provoke cough. The nature of the neuronal mechanisms involved in the afferent component of the reflex is uncertain in humans. It is likely to involve myelinated irritant fibres and intravascular non-myelinated J receptors, which are thought to transmit cough via C fibres as well as myelinated fibres. Agents in the fluids bathing sensory nerves in the airway are important in their state of activation and sensitivity to other stimuli. For example, prostaglandins have been shown to activate and also sensitize the afferent fibres. The central nervous component of the cough reflex may be located to the region of the medulla oblongata and it is now thought that 5-hydroxytryptamine receptors are involved. The efferent part of the reflex involves the nerve supply to the larynx, rib cage and diaphragm and is generated in four distinct phases: inspiration, compression of intrathoracic gas against a closed glottis, explosive expulsion as the glottis opens, and relaxation of the airways. This results in expectoration of foreign debris and mucus from the large airways as a result of the extremely high local turbulent airflows generated by the reflex. Cough contributes little to tracheobronchial clearance in healthy individuals but in chronic bronchitis may account for up to 50% of clearance, compensating for deficient mucociliary transport [2].

The cough reflex can be inhibited by a number of mechanisms. One such physiological inhibitory mechanism is mediated by swallowing, which causes a reduction in coughing. This can be stimulated by the presence of either a solid or liquid in the pharynx, which induces the inhibitory reflex via an unknown mechanism. Opiates have a direct, rather than a sedative, effect on the central nervous system component of the cough reflex since other sedative drugs are without effect. Local anaesthetic agents can effectively abolish the cough reflex via blockade of the afferent signals in the nasopharynx and upper airways. This effect can last a few hours and obviously needs to be borne in mind when advising patients who have undergone fiberoptic bronchoscopy or upper alimentary endoscopy.

### Mucociliary escalator

In healthy subjects cough is not effective in removing small inhaled particles and it is likely that mucociliary transport is entirely responsible for tracheobronchial cleanliness [3]. The mucociliary clearance mechanism works by a complex interaction between cilia, which are a series of projections on the bronchial epithelial cells, and mucus [4]. The mucus forms a 'raft' on top of the cilia, which sweep in a cephalic direction; the effectiveness of cilia in sweeping the mucus is greatly enhanced by small claws at their tips that penetrate the overlying mucus raft (Fig. 4.1). Each of the pseu-

Fig. 4.1 Scanning electron micrograph of the mucociliary escalator showing the mucus 'raft' above and the projections of the cilia below. (Kindly provided by Dr. Peter Jeffery.)

dostratified columnar epithelial cells lining the bronchi possesses about 200 cilia on its surface; calculations have shown that the cilia can carry weights of up to 10 g without slowing. The cilia beat 12–14 times per second and their motor function is mediated by the contraction of fibrils that contain the contractile protein tubulin arranged as nine outer and two central microtubular pairs (see Fig. 1.13, p.12). The biochemical mechanisms serving the ciliary motor are not fully established but there is an important role for dynein, an ATPase protein that forms a major part of the cilium. Dynein appears to derive energy from ATP along the cilium that is then converted into the forces generated by the contractile proteins.

Cilia can survive freezing for up to a month and may beat for several hours after the death of the host. Thus it is possible to assess ciliary motility directly on cytological specimens from nasal and bronchial brushings and to enumerate ciliary beat frequency in epithelial specimens sampled by biopsy. The structure of the cilia can be assessed by electron microscopy. A simple and practical clinical test for ciliary function involves establishing the time taken for saccharin placed in the anterior nares to cause a sweet taste in the mouth (normally less than 30

min). Other more complex methods of assessing mucociliary clearance *in vivo* include direct cine-bronchographic measurement of the movement of small Teflon discs [5] and assessment of the rate of clearance of radio-aerosols by external imaging techniques [6].

Mucus is secreted by the goblet cells and submucosal glands of the first several bronchial generations. A variety of chemical mediators have been implicated in the control of mucous secretion. Neuropeptides, including substance P, vasoactive intestinal peptide and bombesin, vagal stimulation and acetylcholine cause increased mucous secretion. In health, mucus is composed of 95% water, mucous glycoproteins or mucins, and a variety of other proteins (see below), which although present in low concentration probably play an important part in the defence of the bronchial tree. The main physical functions of mucus are to trap and clear particles, dilute noxious influences, lubricate the airways and humidify inspired air. The viscoelastic or rheological properties of mucus are probably controlled by different concentrations of the various mucins and are important in determining adequate mucociliary transport. There is now a great deal of interest in abnormal constitution and rheological properties of mucus [4], and in the deranged mucociliary clearance in cystic fibrosis. In this condition the mucus appears to be abnormally viscous and has markedly altered rheological properties that contribute to dysfunction of the mucociliary clearance mechanism (see Chapter 30).

A number of external factors may also reduce mucociliary clearance, either by interfering with ciliary function or by causing direct ciliary damage. These include cigarette smoke, pollutants, local and general anaesthetic agents, bacterial products and viral infection. In severe asthma it is thought that some eosinophil products, such as major basic protein, may have detrimental effects on ciliary function. There is also an autosomal recessive condition (occurring with a frequency of about 1 in 30 000 of the population) called primary ciliary dyskinesia in which defects in ciliary dynein may be associated also with male infertility and situs inversus. Primary dyskinesia is associated with repeated sinusitis and respiratory infections that often progress to persistent lung suppuration and severe bronchiectasis, thereby underlining the importance of normal ciliary function in antibacterial lung defences.

## Surfactant

As discussed in Chapter 1, surfactant is a complex surface-active material lining the alveolar surface that reduces surface tension and prevents the lung from collapsing at resting transpulmonary pressures. It also provides a simple but elegant mechanism for alveolar clearance, since at end-expiration surface tension decreases and the surface film moves from the alveolus towards the bron-

chioles, thus carrying small particles towards the mucociliary transport system.

Surfactant is synthesized by the alveolar type II pneumocytes and comprises phospholipids, neutral lipids and at least four different specific proteins, known as Sp-A, Sp-B, Sp-C and Sp-D. It is now recognized that in addition to promoting the surface-active properties of surfactant these proteins have important roles in host defence. There are now many studies showing that surfactant from normal lungs exerts a variety of influences on alveolar macrophages, including chemotaxis and enhancement of phagocytosis and killing of microorganisms.

Normal surfactant also enhances local pulmonary non-specific immune defence mechanisms by suppressing the development of specific T lymphocyte-mediated immune responses to inhaled antigens and T-cell proliferation. It is also likely that surfactants exert influences on neutrophil functions including neutrophil adherence.

## Surfactant proteins

Sp-A is the most abundant protein in surfactant, accounting for 3 mg of protein per 100 mg of phospholipids. At an ultrastructural level it closely resembles the complement component C1q and interacts with a C1q receptor (or 'collectin' receptor). It has been shown to enhance alveolar macrophage phagocytosis of microorganisms including *Staphylococcus aureus*, and may also be important in *Pneumocystis carinii* recognition. Sp-A adheres to pollen grains and enhances FcR- and CR1-mediated phagocytosis of a variety of particles opsonized with IgG or C3b, respectively. Sp-D may also share many of the effects of Sp-A on inflammatory cells and macrophages. Surfactant proteins have also been shown to inhibit endotoxin-stimulated release of interleukin (IL)-1, IL-6 and tumour necrosis factor (TNF).

The *in vivo* significance of these observations is uncertain. Nevertheless, surfactant can be damaged by a number of noxious stimuli, and alterations of surfactant both quantitatively and qualitatively are thought to be important mechanisms in the pathogenesis of adult respiratory distress syndrome (see Chapter 27). This may manifest not only as effects on lung function and gas exchange but also by contributing to the known susceptibility of the injured lung to bacterial colonization and infection. There are also implications for surfactant replacement therapy in both neonatal and adult respiratory distress syndrome, since the artificial surfactants do not contain these protective proteins.

## Other protective proteins of the lung lining fluid

Apart from the surfactant proteins, a number of other

**Table 4.1** Protective proteins in lung lining fluids.

<i>Antibacterial</i>
Surfactant proteins (especially SpA and SpD)
Immunoglobulins (especially IgA)
Defensins
Lactoferrin

$\alpha_1$ -Proteinase inhibitor
$\alpha_1$ -Antichymotrypsin
$\alpha_2$ -Antimacroglobulin
Secretory leukoproteinase inhibitor
Elafin
Tissue inhibitors of metalloproteinases

proteins are present in lung fluids and are important in lung defences (Table 4.1). These may be derived from plasma (e.g. albumin, antiplasmin,  $\alpha_2$ -macroglobulin and transferrin), by secretion from local epithelial cells (a variety of antiproteinases), airway macrophages and lymphocytes or inflammatory cells (e.g. defensins, lysozyme, lactoferrin), or by selective epithelial transport (IgA). In the event of an inflammatory response the local availability of plasma-derived proteins increases greatly during the exudative phase of oedema, and this would obviously deliver more complement antiproteinases, immunoglobulins, cytokines, etc. to the inflamed site.

**Immunoglobulins**

Normal lung secretions contain all the immunoglobulins present in plasma but in different proportions [7]. By comparison with plasma, IgA is greatly in excess and there are only small contributions from IgG and IgM. In the absence of disease, immunoglobulins are produced by local lung tissues, probably from B lymphocytes and plasma cells scattered throughout the bronchial tree, often in association with bronchial epithelial cells. The role in health of collections of lymphocytes in the bronchial tree, the bronchial-associated lymphoid tissue, is uncertain. It may be that these lymphoid aggregates are more a feature in smokers and in patients with chronic respiratory disease. With regards to IgA production it is thought that B lymphocytes produce secretory IgA in the upper airways by a collaborative mechanism involving the epithelial cells. Dimeric IgA is assembled in the plasma cells from two monomeric IgA molecules and joined by another protein called the J chain. Dimeric IgA binds to the secretory component of epithelial cells, leading to formation of a dimeric IgA–secretory component complex that is pinocytosed, transported through the epithelial cell and released from its luminal surface into the airways [8]. The secretory com-

ponent appears to protect IgA from enzymatic attack during bacterial infection and inflammation. IgA is produced in very high concentrations in the upper airways and probably serves a number of important anti-infective roles, not all of which have been fully elucidated. However, IgA deficiency is associated with local defects in immunity to bacterial infections [9].

**Defensins and other proteins with antibacterial effects**

Defensins are a family of cytotoxic cationic peptides secreted mainly by leucocytes [10]. Their antibacterial effects correlate with their charge, which is determined by the arginine content of the molecule. Defensins are able *in vitro* to kill a variety of Gram-positive organisms, fungi and viruses. Lactoferrin is an iron-binding protein, the antibacterial action of which is in part related to competition with iron, an essential growth factor for certain bacteria. Lysozyme is a highly cationic protein able to disrupt a range of bacteria that contain susceptible cell wall peptidoglycans.

**Complement proteins**

Most of the proteins involved in the complement system have been identified in lung secretions. However, during inflammation their delivery to the lung is probably greatly increased by plasma exudation. Alveolar macrophages are able to secrete C3a, C3b and C5a. Patients with C3 deficiency have recurrent upper and lower respiratory tract infections, particularly with *Streptococcus pneumoniae* and *Haemophilus influenzae*. Therefore C3 is likely to play a key role in bacterial defences of the lung, perhaps because of its action as an opsonin (via C3bi), thereby enhancing the removal of bacteria by macrophages and other phagocytes.

**Antiproteinases**

Lung secretions contain a variety of antiproteinases, including those of high molecular mass ( $\alpha_1$ -proteinase inhibitor and  $\alpha_2$ -antimacroglobulin) and those of low molecular mass (secretory leukoproteinase inhibitor (SLPi) and elafin). Many of these agents may be derived from alveolar macrophages and airway epithelial cells, and during inflammatory and injurious processes the rate of secretion of these important protective agents is likely to be greatly enhanced. It is widely agreed that these enzyme inhibitors play an important part in the antiproteinase shield necessary to protect healthy local tissue against damage that would otherwise inevitably accompany the release of proteinases by inflammatory cells. During an acute inflammatory response it seems likely that the small molecular mass antiproteinases such as SLPi and elafin are

more effective in the restricted intercellular microenvironments created by neutrophils tightly adherent to endothelial/epithelial cells or basement membrane/matrix proteins [10].

#### **$\alpha_1$ -Proteinase inhibitor**

Together with antithrombin III, antiplasmin and  $\alpha_1$ -antichymotrypsin,  $\alpha_1$ -proteinase inhibitor is a member of the serpin family that inhibit enzymes of the metalloproteinase type. It is particularly effective against neutrophil elastase, which has been specifically implicated in a number of inflammatory diseases of the lung. Although  $\alpha_1$ -proteinase inhibitor is highly effective against elastase, it may well be too large a molecule to work efficiently in the restricted microenvironment between neutrophils adherent to target cells or tissue matrices. It is also quite vulnerable to damage by oxidizing agents, such as those contained in cigarette smoke.

#### **$\alpha_1$ -Antichymotrypsin**

$\alpha_1$ -Antichymotrypsin is also a member of the serpin family. Although its concentration in serum is low, its concentration in bronchial secretions is high, suggesting that either it is secreted locally or there is an active concentration mechanism in the bronchial mucosa. It does not inhibit neutrophil elastase but is extremely effective against cathepsin G. A genetic defect of this protein has recently been described and has been linked with chronic lung diseases, suggesting that it may well have an important role in lung defence against proteinase attack.

#### **$\alpha_2$ -Antimacroglobulin**

$\alpha_2$ -Antimacroglobulin, like  $\alpha_1$ -proteinase inhibitor, is a major serum inhibitor of proteolytic enzymes, and has a wide range of effects against those proteinases, including the metalloproteinases, not influenced by  $\alpha_1$ -proteinase inhibitor. Like  $\alpha_1$ -antichymotrypsin it is present in significant quantities in bronchial secretions.

#### **Secretory leukoproteinase inhibitor**

SLPi is produced by the submucosal glands in the bronchi and also by the epithelial cells of the small airways. It is found in significant concentrations in the sputum and bronchoalveolar lavage fluid but is barely detectable in the serum. Its low molecular size may allow it access to the restricted intercellular microenvironments that appear to be necessary for neutrophil-mediated injury (see Chapter 27). SLPi is an extremely potent and rapid inhibitor of neutrophil elastase but can also inhibit a number of other serum proteinases, including cathepsin G, trypsin and

chymotrypsin. SLPi forms more than 80% of the antielastolytic capacity of the bronchial secretions and is thought to be an important component of the antiproteinase shield protecting the lung.

#### **Elafin**

Elafin is another small molecular mass (6 kDa) antiproteinase that, like SLPi, is extremely effective against neutrophil elastase. It can be distinguished from SLPi biochemically in that it does not inhibit trypsin, chymotrypsin or cathepsin G.

#### **Tissue inhibitors of metalloproteinases**

A number of inhibitors of this type have been described. They are secreted by fibroblasts and alveolar macrophages and are able to inhibit all metalloproteinases. Again, because of their small molecular mass (around 25 kDa) they may have access to sites of metalloproteinase action that exclude the larger molecules such as  $\alpha_2$ -antimacroglobulin (molecular mass 780 kDa).

#### **Alveolar macrophage**

Alveolar macrophages are derived from blood-borne monocytes that originate in the bone marrow [11]. They are highly differentiated cells that normally patrol the alveolar lining, where they probably live for several weeks (Fig. 4.2; see also Fig. 1.16). Their accessibility to bronchoalveolar lavage has greatly facilitated the *ex vivo* study of the various functions of these highly versatile cells (Table 4.2). It has been known for some time that alveolar macrophages possess marked phagocytic ability, being able to ingest and destroy pathogenic bacteria and particles, although their capacity to generate mediators of central importance in the initiation of inflammation and to present antigen in the initiation of immune responses has been fully recognized only recently. The alveolar macrophage has a vast array of receptors on its surface (Table 4.3) and can respond to a wide range of external stimuli and subsequently generate a wide range of secretory products. In the control of the inflammatory response the alveolar macrophage can be considered analogous to a microcomputer, sampling and sensing the external environment and determining whether to initiate or amplify the inflammatory response. It is also likely to assist the inflammatory monocyte-derived macrophages in the scavenging roles required during the aftermath of infections and in the resolution of inflammation. The alveolar macrophage may play further important roles in the processes whereby inflammatory tissue injury is repaired, since it can produce a number of proteins involved in tissue repair processes and can generate a wide range of growth factor cytokines that influence fibroblast

jected to the combined destructive forces of both reactive oxygen intermediates generated via the metabolic burst and a wide range of degradative enzymes that have the capacity to digest proteins, lipids and carbohydrates (Table 4.4). It appears that the local intracellular generation of nitric oxide (NO) is an important defence mechanism against a variety of microorganisms. Activated macrophages also form nitrite (NO<sub>2</sub>) and nitrate (NO<sub>3</sub>). *In vitro* experiments suggest that these products, particularly NO and the peroxynitrite anion, also contribute to the antifungal, antiparasitic and tumoricidal activities of macrophages. Macrophages may also call in reinforcements comprising other phagocytic cells, including neutrophils, monocytes (which then mature into

inflammatory macrophages) and eosinophils, by the generation of specific chemotaxins (see below). Despite the availability of such powerful mechanisms, it is clear that not all phagocytosed particles are effectively destroyed. Minerals such as asbestos and quartz and a number of microorganisms, including *Mycobacterium tuberculosis* and trypanosomes at various stages of their life cycle, are able to resist destruction within macrophages.

### Initiation and control of the inflammatory response

Macrophages can secrete a number of chemotactic proteins, including members of the 5-lipoxygenase and cyclooxygenase pathways (see Chapter 33), which exert important proinflammatory effects, and leukotriene B<sub>4</sub>, which is a specific neutrophil chemotaxin. Perhaps more importantly in terms of chemoattraction, lung macrophages are a potent source of neutrophil chemokines, including IL-8, NAP-1, NAP-2, etc., and also secrete chemokines for monocytes and eosinophils, including MCP-1, MIP-1 $\alpha$  and RANTES. Other macrophage-derived cytokines may have important secondary proinflammatory effects through their influences on other local cells. For example, both TNF- $\alpha$  and IL-1 generated by alveolar macrophages can act on the endothelium to stimulate the expression and activation of surface adhesion molecules necessary for neutrophil adhesion and emigration, but they can also act on local fibroblasts, epithelial cells and endothelial cells to produce IL-8 and other chemokines that attract more neutrophils and thereby amplify the inflammatory response. Thus macrophages are not only able to generate chemoattractants for inflammatory cells themselves but can also indirectly recruit other local cells to help in the initiation of inflammation, thereby exerting further levels of control on the initiation and amplification of the inflammatory response. The acute inflammatory and the allergic inflammatory responses are considered in detail in Chapters 27 and 33 respectively.

### Initiation and control of the immune response

Alveolar macrophages are effective antigen-presenting cells and can display partially degraded antigens on their surface that interact with recirculating T and B lymphocytes, thereby generating clonal expansion and initiating the immune response (see Chapter 33). However, the main cells responsible for this role, dendritic cells, are also present in the lung but are less accessible, more difficult to purify and therefore less easy to study *in vitro*. With regard to antigen presentation, resident alveolar macrophages are not likely to be as effective as recently matured monocyte-derived inflammatory macrophages, or 'professional' dendritic cells. The evolution of an allergic immune response is considered in more detail in Chapter 33.

**Table 4.4** Some secretory products of macrophages.

### Tissue modelling and repair

Alveolar macrophages can secrete proteins, including vitronectin, fibronectin and laminin, that are important in tissue repair. They also secrete a number of growth factor cytokines [12], including platelet-derived growth factor, transforming growth factor  $\beta$  and IL-1, all of which can influence the behaviour of fibroblasts in terms of both proliferation and secretion of collagen and other matrix proteins.

### Pulmonary marginated pool of neutrophils

The neutrophil is the archetypal acute inflammatory cell and is equipped with an armamentarium of granule contents (see Chapter 27) that have probably evolved to aid its rapid transit through tissues and the killing of bacteria such as streptococci. After release from the bone marrow, mature neutrophils remain in the vascular compartment with a half-life of about 6 h. Unlike red blood cells, up to half the neutrophils in the vascular compartment at any given time are not circulating but form the 'marginated pool', which is in dynamic equilibrium with the 'circulating pool' of vascular neutrophils. The marginated pool can be released into the circulating pool by exercise or epinephrine (adrenaline). The vascular bed of the lung and spleen make the most important contributions to the marginated pool and may therefore serve as a source of rapidly releasable neutrophils in time of stress or injury. However, the presence of large numbers of neutrophils loitering in the pulmonary microvascular bed may also be

of local advantage in host defence. Their mobilization and effectiveness is likely to be augmented in local lung responses to inhaled microorganisms or toxins and in the generation of a local inflammatory response to lung invasion by streptococci for example (the role of neutrophils in lung inflammation is considered in Chapter 27). However, there may be a downside to the presence of this marginated pool of neutrophils in pulmonary microvessels: they may put the lung particularly at risk of developing injury in multiple organ failure (see Chapter 27).

The mechanisms underlying the formation of the marginated pool in the lung are uncertain. It is possible that it occurs as a result of low-grade adhesive interactions between neutrophils and lung capillary endothelial cells. However, it is more likely that the rheological properties of neutrophils in pulmonary capillaries are relatively more important in their physiological margination in the lung compared with other microvascular beds. The mean diameter of the pulmonary capillary is 5.5  $\mu\text{m}$ , whereas that of the neutrophil is 7.5  $\mu\text{m}$ . Thus neutrophils are normally required to 'squeeze' through pulmonary capillaries, and minor changes in their deformability or alterations in the fluid pressure gradient across the lung capillary bed would be expected to exert a marked influence on the size of the pulmonary marginated pool. It is of interest that many inflammatory mediators known to be important in neutrophil attraction and sequestration in the lung not only cause increased expression of neutrophil surface adhesive molecules and activation of those already expressed but can also markedly reduce the deformability of neutrophils.

# GENETICS OF LUNG DISEASE

JULIAN M. HOPKIN

Genetics, the study of inherited differences between individuals, is now linked strongly to the discipline of molecular biology, whose aim is to delineate the structure and function of genes, their protein products and other biologically important molecules. A recent explosion in molecular techniques, particularly in molecular genetics, has revolutionized the study of the genetic factors underlying disease. Disorders of the lung have featured prominently in this progress, especially cystic fibrosis (CF) and  $\alpha_1$ -antitrypsin (AAT) deficiency. The extensive range of genetic effects in lung disorder should not be surprising for an outbred species like the human, in whom it is estimated that there is some kind of genetic variation or polymorphism, functional or not, every 500 base pairs (bp) of DNA; even using fairly crude techniques such as protein electrophoresis, it was plain some 20 years ago that many human enzymes (>30%) showed significant genetic variation [1,2].

These genetic effects in lung disease range between (i) monogenic effects (mutations at a single genetic locus) such as CF [3], and (ii) multifactorial and genetically heterogeneous effects, for example those underlying the syndrome of atopy and its associated clinical disorders such as asthma, in which there are crucial interactions between genetic effects and environmental factors that cause disorder and disease [4]. In the future, we will see increasingly subtle genetic factors discovered that may in part explain human susceptibility to disease, for example those that modulate the risk of respiratory infections such as tuberculosis. We will recognize that the genetic heterogeneity underlying common disorders, such as asthma and atopy, may be an important pointer towards the need for different treatments for different individuals with apparently the same clinical syndromes.

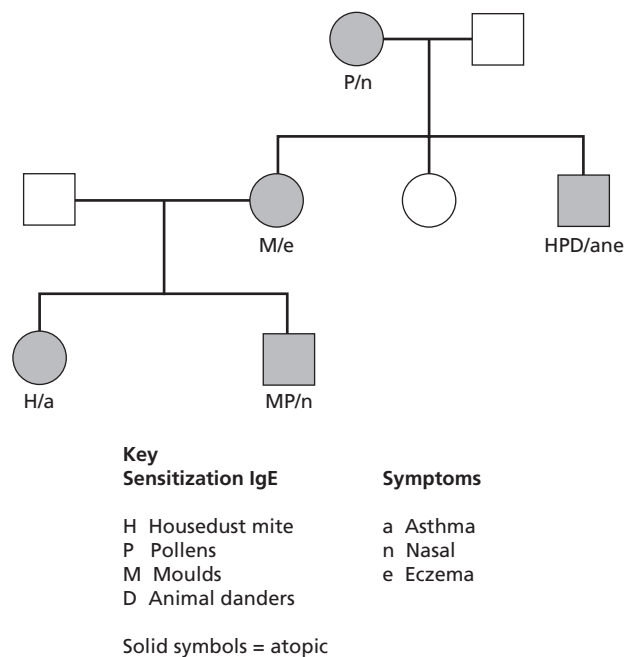

This bright age of molecular reductionism will need a cohort of visionary physiologists and clinicians to create an understandable synthesis of human lung function and disease in all its diversity.

## Genetic counselling

The occurrence of a genetic disorder in a family causes particular distress. Expert genetic counselling is invaluable in providing emotional support, answering questions about the origin of the disease and its likely progress, providing families with estimates of the risk of recurrence in other family members, and indicating what investigations and techniques are available to limit this risk — for example carrier detection, antenatal diagnosis and termination of pregnancy. The genetic counselling process aims to allow families to make their own, but well-informed, decisions on their reproductive future. The recent advances in molecular genetic techniques are having a major impact on this process: molecular DNA assays are now available for antenatal diagnosis and carrier detection in families for many genetic disorders, including CF and AAT deficiency.

## Evidence for genetic effect and the hunt for 'disease genes'

The main clue to a significant genetic effect in the aetiology of a disease lies in the observation that the disorder tends to cluster within families, although it must be recalled that shared familial environmental factors can also produce such aggregation (Fig. 5.1). The pattern of observed aggregation depends upon the genetic contribution to the disorder. When the genetic effect is predominant, i.e. both necessary and sufficient for causing the disease, monogenic or Mendelian patterns of inheritance are observed, for example autosomal recessive in CF. However, note that different patterns of inheritance may be observed in different families if there is genetic heterogeneity (different variants or mutations at one or more than one genetic locus can produce the same clinical syndrome) [5,6]. When a disorder is multifactorial in origin, i.e. when both genetic and environmental factors must interact to cause the disease, the incidence of disease in close relatives, for example siblings, is much lower than

**Fig. 5.1** Familial aggregation of atopy: solid symbols denote atopic individuals (elevated total serum IgE or specific IgE to any one or more common inhaled antigens) but note that the pattern of specific allergen sensitization and clinical disorder varies.

for the monogenic disorders but is of course higher than in the general population.

Twin studies have proved to be useful in clarifying whether genetic effects are important in causing disease. If they are, then monozygous twins (who share all their genes) will be significantly more concordant for the disorder than dizygotic twins (who on average share 50% of their genes). For example in atopy, twin studies suggest that 50% of the variability of total serum IgE levels can be attributed to genetic effects [7]; restated, the heritability (the portion of a disease due to genetic effect) for total serum IgE levels is 50%. Heritability ( $h^2$ ) can be estimated from twin studies using relatively simple formulae [8]; the estimate for  $h^2$  of decline in lung function (forced expiratory volume in 1 s) was found to be 67% in Swedish twins [9].

The discovery of ‘disease genes’ has now become a major enterprise and is an integral part of the Human Genome Project [10,11]. Such ‘disease genes’ happen to have mutant or variant forms that are present in some members of the population and which promote or cause disease in these individuals. Investigating the origin of a genetic effect, i.e. the discovery of the genetic locus at which variants confer risk of disease, has been pursued in two major ways in recent years: (i) the positional cloning (or reverse genetics or linkage) approach, and (ii) the candidate gene approach [12].

**Positional cloning**

In positional cloning [13,14], the emphasis of the initial investigation is to delineate some chromosomal region for which one can demonstrate co-inheritance of local DNA polymorphisms with the disorder/disease of interest in some families with the disorder, i.e. demonstrate *genetic linkage* [15]. Following this, the chromosomal region can be ‘mapped’ [16], using other local polymorphisms or markers, in order to identify the polymorphism that shows the most perfect co-inheritance with the disorder; this provides evidence for more precise localization of the disease locus. Structural genes, those that encode proteins, can then be identified and cloned from around such closely linked polymorphic markers and the search for mutations in appropriate cloned genes started. Ultimately, a gene with a mutation or variant that shows association with the disorder in unrelated individuals will be found [17,18]; then functional experiments on the variant protein product are conducted. This kind of positional cloning exercise represents a scientific *tour de force* and the discovery of the CF gene and its protein product is a prime example of its successful deployment [13]. First, genetic linkage of CF to the mid-portion of chromosome 7q was discovered, then the region was laboriously but accurately mapped [16], local candidate genes identified and cloned, and ultimately a trinucleotide deletion discovered signifying the loss of phenylalanine at position 508 ( $\Delta F508$ ) for a membrane-associated protein [17].  $\Delta F508$  was very strongly associated with CF, accounted for 70% of CF mutations and has been shown to critically alter the chloride-transporting properties of a membrane-associated protein, since denoted the cystic fibrosis transmembrane regulator (CFTR) [19,20].

Positional cloning can also be used for investigating the genetics of multifactorial disorders, although the necessary interaction between environmental factors and the actions of variants at often more than one locus make the investigative process more difficult [14]. Even when dealing with apparently the same clinical disorder, the genetic locus involved may be different in different families; this genetic heterogeneity makes gene hunting more difficult and may lead to confusion when replication of linkage is attempted. For example, an early report of linkage of atopy to chromosome 11q13 [21] had to wait some 7 years before independent, large-scale replication was achieved [22]; current data suggest that the  $\beta$  subunit of the high-affinity IgE receptor is the principal candidate gene at the location [23]. Also in multifactorial disorders there is usually no clear mode of inheritance, and the necessary interaction of independent causal factors can lead to diagnostic errors in categorizing individuals within families as diseased or not; for example some individuals may not have the disease but will have inherited the genetic propensity, whilst others may have the disease due

**Table 5.1** Genetic linkage by sibling-pair analysis. The shared phenotype for the sibs is shown under IgE serotype. Sharing of one (1) or neither (0) allele from either parent for a polymorphism within the T-cell receptor  $\alpha/\delta$  region on chromosome 14q is shown. This demonstrates linkage since the expected (null hypothesis) ratio of 1 to 0 is 50:50.

IgE serotype	Alleles shared		$\chi^2$	P
	1	0		
House-dust mite (HDM)	71	44	6.34	0.01
Grass pollen	74	48	5.54	0.02
IgE > 70%	79	46	8.71	0.003
Der p I (HDM)	57	25	12.5	0.0004
Der p II (HDM)	66	34	10.2	0.001
Fel d I (cat)	42	15	12.8	0.0004

to great environmental burden but have not inherited significant genetic risk factors. The method of *affected sibling-pairs analysis* has recently emerged as a useful technique for addressing these difficulties [24,25]; the method needs no prior decision on mode(s) of inheritance and it limits (because of its inclusion of affected individuals only) the effect of variable genetic penetrance (Table 5.1). The sib-pair method has been used very productively in investigating type I diabetes mellitus [26] and has shown that effects at some six genetic loci underlie the development of this disorder; the sib-pair method was allied to semi-automated, fluorescent methods of detecting microsatellite length polymorphisms at some 300 locations that effectively covered the ‘genome’ [27]. Similar searches conducted for atopy and asthma have also emphasized important genetic heterogeneity [28,29].

**Candidate gene**

The candidate gene approach offers a far more direct method but represents a form of inspired molecular-pathological guesswork that may or may not be successful for any particular exercise. The fruitful work on the globin genes involved in sickle-cell disease and the thalassaemias represented the first attempt at this kind of approach. In this procedure, variants at a particular genetic locus are suspected of causing a disease because of the known functions of the gene’s protein product and through knowledge of the pathology of the disorder. For example, interleukin (IL)-4 plays an important role in determining the switch from IgM to IgE synthesis in B lymphocytes [30] and enhanced IgE synthesis is a recognized part of the atopy syndrome and its associated clinical disorders asthma and rhinitis [31]. Based on this knowledge, Marsh and colleagues [32] considered the loci for IL-4 and closely related cytokines on chromosome 5 as candidate genes for atopy; they conducted linkage studies using microsatellite polymorphisms within the cytokine cluster on chromo-

some 5 and sib-pair analysis for low total serum IgE levels. They found evidence for genetic linkage and this has been replicated; the locus involved awaits identification. The candidate gene approach need not use linkage or sib-pair analysis; intragenic polymorphisms can be used directly in a case-control genetic association study.

**Syndromes and genetic effects**

This account of respiratory syndromes/disorders with significant genetic input is loosely classified according to the respiratory structure or function mainly affected.

**Bronchial tree**

**Cystic fibrosis**

CF is the most common fatal autosomal recessive disease in Caucasians with an incidence of 1 in 1500 and carrier frequency of 1 in 22. Since CF is characterized by mucus of low water content [33] that is moved with great difficulty, the major impact is on mucus-secreting organs and results in the secondary clinical disorders of meconium ileus, pancreatic destruction (with malabsorption and diabetes mellitus), sinus disease, bronchiectasis, and infertility in males. Based on a successful positional cloning investigation [16–18], we now know that CF is due to mutations in a gene on chromosome 7q31.2 [13]. The gene is large, with 27 exons spanning 250 kb of DNA, and encodes an mRNA of 6.2 kb and a protein of 1480 amino acids, CFTR. CFTR is a cyclic AMP-regulated chloride channel with transmembrane domains forming its channel, an R domain and nucleotide-binding domains, which are involved in coupled ATP hydrolysis and opening and closing of the channel (Fig. 5.2) [3]. CFTR is expressed in specialized epithelial cells, including nasal and tracheal epithelium and submucosal glands. Disorder of CFTR leads to

**Table 5.2** Percentages of cystic fibrosis chromosomes with certain CFTR mutations in different population groups.

\* In Black Americans the frequency of ΔF508 is about 38%.

defective electrolyte transport; defective chloride transport has been shown for the apical membrane of epithelial cells from the airways, pancreas and sweat glands [19,20].

The commonest mutation is a 3-bp deletion causing loss of phenylalanine at amino acid position 508 (ΔF508) and is the mutation on 81.2% of CF chromosomes in the UK [17]. Like many other inherited disorders, careful genetic analysis shows that a great number of mutations in the same gene can result in the disorder. So far, over 500 pathological mutations of CFTR have been recognized, although six to eight mutations account for some 90% of the mutations in any population; however, there are significant differences in the relative frequencies of mutations worldwide [3] (Table 5.2). One provisional classification categorizes CF mutations into class I mutations with defective protein production, class II mutations with defective protein processing (including ΔF508), class III mutations with defective regulation of CFTR, and class IV mutations showing defective conduction through the channel. Studies continue on the association between particular genotypes and phenotype (including the severity of lung disease, pancreatic involvement, age at *Pseudomonas* colonization) but these are not easy because different mutations often occur in combination in those with the disease; however, ΔF508 does correlate with severe pancreatic disease. One set of CFTR mutations is associated with isolated congenital bilateral absence of the vas deferens without systemic CF [34].

Genetic counselling strategies in CF have been greatly aided by the advances in molecular genetics. In any family with an affected child, the parents are obligate heterozygotes and the risk of CF in any further child is 1 in 4. Two-thirds of the normal siblings will be carriers but the risk of CF in their children is relatively low (i.e.  $2/3 \times 1/22 \times 1/4 = 1/132$ ). Molecular diagnosis for CF is well established, being based on direct mutation analysis. In the family with an affected child it is particularly valuable for prenatal diagnosis on chorionic villous samples and can also be used for carrier detection within families. Significant ethical and logistic issues are attached to the application of carrier and neonatal screening in the

general population, but a start has been made in some communities [35,36].

Approaches to local gene therapy have been piloted for nasal and bronchial epithelium, using viruses or liposomes as vectors (or carriers) for normal cDNA of CFTR; transient correction of electrophysiological abnormalities has been achieved. However, a number of major practical difficulties, not least the need for prolonged expression, remain to be overcome before gene therapy becomes a realistic clinical option [37,38].

### Immotile cilia syndrome

The immotile cilia syndrome or primary ciliary dyskinesia is a rare genetically heterogeneous disorder in which inheritance is usually autosomal recessive [39]. Its incidence is approximately 1 in 30 000. The ciliary abnormality can normally be observed on electron microscopy of a ciliated mucosal biopsy or spermatozoa from an ejaculate. Defects of the ciliary axoneme are visualized, the most common being lack of dynein arms (see Fig. 1.13). The impaired ciliary function results in impaired clearance of mucus and leads to chronic rhinitis and bronchiectasis, sinusitis (often with absence of the frontal sinuses) and ear disease. As in CF, males are normally infertile. Kartagener's syndrome is one clinical subgroup of the immotile cilia syndrome where there is also dextrocardia or situs inversus (the result of random organ rotation in development as a result of poor ciliary function). The genetic heterogeneity of the syndrome reflects the likelihood that many genes, and their proteins, participate in the construction of the normal cilium and that genetic mutation affecting any one of them may impair ciliary function. None of these genes has been formally identified.

### Atopy and associated asthma and rhinitis

Atopy, the state of allergic disorder to common antigens such as the house-dust mite and pollens, is a common and complex disorder in which heterogeneous genetic influences interact with the environment to result in the

immunological abnormality and its associated clinical disorders that include asthma and rhinitis [4]. Asthma and rhinitis have other causes besides atopy.

Twin studies show that both genetic and environmental factors are important and suggest that the greatest genetic contribution acts on the immunological phenotype rather than that of clinical disease *per se* [7]. The highest concordance (71%) in monozygotic twins is for allergic response to *any* one or more common inhaled allergens, the concordance for this characteristic in dizygotic twins being 36% [7].

Genetic linkage studies for both atopic IgE responses and asthma (or bronchial hyperreactivity) have identified a whole set of linkages on many chromosomes [21,28,29,31,40]. The first demonstration of genetic association and accompanying functional change was for the IL-4 receptor IL4R $\alpha$  [41]. Substitution of isoleucine for valine in the extracellular domain of the receptor (position 50) associates strongly with atopic asthma in Japanese children; in transfection experiments Ile50Val upregulates the cellular response to IL-4 challenge and leads to increased secretion of IgE. A second variant, Arg576Glu, has been associated with defective binding of the negative regulator SHP-1 and the hypereosinophilic syndrome [42].

On chromosome 14, the principal candidate locus is the  $\alpha\delta$  complex of the T-cell receptor and the linkage may be with allergen-specific IgE responses rather than general atopy; gene mutations associated with atopy are yet to be described [40]. Chromosome 5q has several candidate loci, including those encoding a number of relevant cytokines, (IL-4, IL-13, IL-5); genetic linkage of asthma and total serum IgE levels has been shown to this region; the locus and relevant mutations await identification [31,32]. On chromosome 11q, Fc $\epsilon$ RI- $\beta$  remains the clearest candidate but no functional action of any variant has been determined.

Although variants of human leucocyte antigens (HLA) are associated with allergic reaction (and production of IgE) to fractions of certain allergens [43], for example ragweed *Amb aV* [44], there is little evidence to suggest that these variants enhance the risk of clinical disorder; this may be due to the immunological complexity of whole allergens or the possibility of 'molecular promiscuity' at antigen presentation and T-cell recognition [45,46].

The relative importance of these different loci, and the question as to which of them impact on IgE responses or asthma *per se*, is likely to be ultimately clarified in large-scale population association surveys. In the long term, novel therapies may target some of the commonest of the protein variants and, furthermore, may be administered specifically to those with the matching inherited molecular pathology. However, it is noteworthy that the recent rise in atopy and asthma emphasizes the importance of interactive environmental effects [47].

## Pulmonary parenchyma

### $\alpha_1$ -Antitrypsin deficiency

Emphysema, the pathological entity of destruction of alveolar walls with secondary alveolar dilatation and disruption of ventilation-perfusion matching, is mainly the consequence of cigarette smoking. The observation that significant AAT deficiency is a major risk factor for the development of accelerated emphysema in cigarette smokers was made originally by Laurell and Eriksson over 30 years ago and has led to the proteolysis hypothesis for emphysema in smokers [48]. This proposes that proteases, such as elastase, are released from pulmonary neutrophils and macrophages 'excited' by cigarette smoke. The actions of the elastase on supportive tissue in the lung is opposed by the serine protease inhibitor (serpin) AAT. When AAT is deficient or when smoking is very heavy, the balance falls in favour of tissue destruction and the development of emphysema. Additionally, there is evidence that free radicals in cigarette smoke oxidize a critical methionine residue at the active site of AAT causing a reduction in its inhibitory activity against elastase [49].

AAT is a glycoprotein (molecular mass 52 kDa) and is encoded at the Pi (protease inhibitor) locus on chromosome 14q32.1. The gene shows alternative splicing in that the mRNA for AAT is longer in the macrophage than in the hepatocyte. Many pathological mutations of the AAT gene have been described, the commonest of which is the PiZ allele that causes substitution of lysine for glutamic acid at position 342. ZZ homozygotes have some 20% of normal AAT levels in plasma and therefore correspondingly reduced levels in the lungs. Z variant molecules tend to polymerize (Fig. 5.3) and are not effectively transported from the hepatocyte where AAT is normally produced [50]; therefore many individuals with ZZ variants develop liver disorder; 10% develop hepatitis with jaundice in infancy and some 50% show disturbances of liver function tests [51]. Other variants include the S (valine for glutamic acid at position 264) and null forms. The S variant molecules do not fold correctly, have a short half-life and effectively reduce AAT levels to 60% of normal [52].

Clinically significant deficiency of AAT arises only in homozygotes (ZZ or null/null) or compound heterozygotes for two different deficiency alleles (e.g. SZ) and therefore AAT deficiency-induced emphysema is an autosomal recessive disorder. In deficient individuals, the most important practical point in management is absolute avoidance of cigarette smoking [53]. Replacement of AAT protein, now available as a molecular engineered product, can increase lung levels when administered by infusion or aerosol inhalation, although trials showing clinical impact are awaited [54,55].

In a family with an affected individual, the risk of AAT

**Fig. 5.3** A schematic figure of  $\alpha_1$ -antitrypsin molecules showing the site of the Z variant. This leads to interaction between the head of one molecule and the tail of the next and hence polymerization.

deficiency in a further sibling is 1 in 4 and molecular prenatal diagnosis is established. The risk to the children of normal but carrier siblings is very small since the incidence of severe AAT deficiency alleles in the population is low.

#### Miscellaneous rare disorders

Pulmonary alveolar proteinosis is a rare heterogeneous disorder characterized by the accumulation of PAS-positive proteinaceous material in the alveoli. It can be secondary to malignancy or infection, for example histoplasmosis. In its infant form it is usually fatal and in some families is probably a genetic disease. One study has reported absence of surfactant protein B and its mRNA but markedly increased amounts of surfactant protein C in the alveoli in one family with two affected siblings [56].

Rare but striking reports of familial aggregation of early-onset diffuse alveolitis and pulmonary fibrosis are recorded but their molecular genetic origins are obscure.

In pulmonary alveolar microlithiasis, there are multiple minute calcifications in the alveoli producing a typical

radiographic appearance. Affected sib-pairs are well described and the observation of consanguinity suggests a very rare autosomal recessive disorder, of currently obscure molecular genetic origin.

#### General genetic syndromes with parenchymal lung involvement

A number of well-described genetic syndromes may display a relatively minor pulmonary component, for example diffuse interstitial pulmonary infiltrates on chest radiography is recorded in a number of inborn errors of metabolism such as Farber's lipogranulomatosis, Niemann-Pick disease type A and Gaucher's disease types I and III. Lethal pulmonary involvement may occur in lysinuric protein intolerance.

The molecular genetic pathology of these disorders is being increasingly characterized. Niemann-Pick disease [57] is a consequence of mutations in the gene for acid sphingomyelinase and results in the development of abnormal 'Niemann-Pick cells', histiocytes whose cytoplasm is filled with lipid droplets or particles. Particularly severe pulmonary involvement in Niemann-Pick disease type B is accompanied by infiltration of these abnormal cells into the substance of the lung and also its lymphatics and vessels [58]. In Gaucher's disease [59], a lysosomal glycolipid storage disorder characterized by the accumulation of glucosylceramide (glucocerebroside), there are mutations in the gene on chromosome 1 encoding the enzyme  $\beta$ -glucosidase. Though pulmonary involvement is rare, it is severe and progressive when present; pathology shows infiltration with Gaucher monocytes/macrophage cells that exhibit characteristic tubular cytoplasmic inclusions.

In the phakomatoses, for example neurofibromatosis or tuberous sclerosis, pulmonary involvement may be observed in the form of pulmonary fibrosis, bulla formation or leiomyomatosis [60].

In Marfan's syndrome, there is not surprisingly an increased risk of spontaneous pneumothorax. There is a clear clinical impression that many young individuals presenting with spontaneous pneumothorax are, whilst not plainly marfanoid, rather asthenic and tall. They may ultimately prove to have genetically determined mild connective tissue disorder. In some subjects with Marfan's syndrome apical bullae are present; more rarely, congenital cystic lung disease may be found [61].

#### Immune system

The lung is constantly exposed to the risk of infectious disorder and there are well-recognized genetic syndromes that predispose to chest infection. Many other genetic variants, with more subtle effects on the risk of infections such as tuberculosis, are likely to be discovered.

### Immunoglobulin deficiency

Antibody deficiency may be primary or secondary (for example to protein loss in renal or bowel disorder). X-linked and autosomal recessive types of the primary form are described and make infection with encapsulated bacteria and mycoplasmas common and severe [62]. Variable combinations of IgA and IgG subclass and IgM deficiency are recognized. The clinical picture may be of repeated pneumonias, with typical systemic upset, or of bronchiectasis with chronic sepsis.

### Combined deficiency of T and B lymphocyte function

Severe combined immunodeficiency (SCID) is a genetically heterogeneous syndrome with profound functional deficiency of both cellular (T-cell) and humoral (B-cell) immunity. In the X-linked form of the disease, most of the mutations are in the  $\gamma$  chain of the cellular receptor for the cytokine IL-2 [63]. Recessive disease in most cases is due to mutations in the purine catabolic enzyme adenosine deaminase (ADA); notably, successful gene therapy has been achieved for ADA deficiency [64]. In SCID, symptoms start in infancy with failure to thrive, diarrhoea due to parasitic and viral infections and pneumonia due to *Pneumocystis carinii*, an organism that typically requires effective T-lymphocyte function for its control.

Ataxia telangiectasia is a more complex autosomal recessive disorder that includes variable immune deficiency, cerebellar ataxia and a propensity to develop leukaemias; one locus of the disorder has been mapped to chromosome 11q22 [65]. Wiskott-Aldrich syndrome, which includes combined immune deficiency, is X-linked. Haemorrhage due to thrombocytopenia, autoimmune disorder and a tendency to malignancy may occur. The locus is unidentified.

### Leucocyte abnormalities

Chronic granulomatous disease, associated with recurrent pyogenic infection of the respiratory tract, skin and lymphoid tissue by catalase-positive bacteria and fungi, is genetically heterogeneous. Oxygen-dependent microbial killing is crucial in phagocytes and the process is mediated by a multicomponent NADPH oxidase, the four major oxidase components being encoded at different chromosome locations: 1q, 7q, 16p and Xp. The most frequent form is X-linked and due to mutation in the gene for the major subunit of cytochrome *b* [66].

Another important property of the phagocyte is accumulation at the site of infection, which in turn is dependent upon adhesive properties of the cell and mobility. In leucocyte adhesion deficiency, an autosomal recessive condition, there are mutations in the gene for CD18, the  $\beta$  subunit of  $\beta_2$ -integrin [67].

### Complement

The complement system, a series of plasma proteins and membrane receptors, plays an essential role in the propagation of inflammation and host defence. Deficiencies have been described for many of its components. Deficiency of C3, an autosomal recessive disorder, increases susceptibility to encapsulated bacteria because of the deficiency of C3b-dependent opsonization [68,69].

### Vascular system

#### Pulmonary embolism

Pulmonary embolism, due to venous thrombosis, is a common and important pulmonary syndrome. There is increasing recognition of genetic deficiencies underlying the disorder in some individuals, particularly those with early onset of disease, unusual sites of venous thrombosis and recurrent disease [70].

Antithrombin is one of the serpins acting on thrombin and other factors in the clotting cascade to inhibit their function; 30 deficiency-causing mutations have been recognized in the gene for antithrombin on chromosome 11q23 [71]. Deficiency is inherited as an autosomal dominant but, because the clinical course is variable, the clinical history cannot reliably exclude the defect. Lower limb venous thrombosis and pulmonary embolism are the commonest clinical problems, although thrombosis may occur in mesenteric, cerebral and other veins.

Activated protein C is a serine protease that has an anticoagulant effect by the inhibition of activated factors V and VIII; this effect requires protein S as a cofactor (see below). Some 30 or so deficiency-causing mutations have been recognized in the protein C gene on chromosome 2 and cause an autosomal dominant pattern of familial deep vein thrombosis and pulmonary embolism [72]. As in antithrombin III deficiency, thrombosis may occur at unusual sites, such as in cerebral and splenic veins.

Protein S deficiency occurs as an autosomal dominant thrombotic disorder that is not clinically distinguishable from protein C deficiency.

Resistance to activated protein C is a relatively common variant due to a point mutation in the factor V gene, the so-called Leiden mutation [73]. In numerical terms, this abnormality is an important cause of venous thrombotic disease in the population [74].

#### Miscellaneous rare syndromes

Pulmonary arteriovenous fistulas may occur as single or multiple lesions and may be sporadic or genetic disorders. The clearest form of the latter is as part of the Osler-Rendu-Weber (hereditary haemorrhagic telangiectasia)

syndrome, a genetically heterogeneous autosomal dominant disorder [75,76]. In this disease, the pulmonary lesions usually are multiple and asymptomatic. However, on bleeding, they can cause haemoptysis, breathlessness and chest pain.

There are a number of reports of primary pulmonary hypertension clustering in families, although this is rare and its mechanism, if distinct from a thrombotic tendency, is unknown.

### **Pulmonary function/neuromuscular disorders**

There are many genetic syndromes of the neuromuscular system that can cause secondary respiratory insufficiency or failure with a tendency to recurrent chest infection because of impaired coughing. The most notable are the muscular dystrophies (e.g. the X-linked recessive Duchenne muscular dystrophy), dominantly inherited myotonic dystrophy and autosomal recessive acid maltase deficiency (type II glycogenosis) [77]. In acid maltase deficiency, diaphragmatic involvement is common and patients may therefore present with respiratory failure [78].

### **Pharmacogenetics**

Idiosyncratic reactions to various therapeutic drugs, which result in a great range of pulmonary disorders, are well recognized. The response of patients to therapeutic agents administered for lung disease also varies both in terms of therapeutic response and toxicity. A number of factors underlie such responses, including age, state of nutrition and hepatorenal function, but in a significant proportion there may be discrete underlying genetic causes though relatively few have been well characterized [79].

The cytochrome P450 enzymes are a large family of haemoproteins that metabolize foreign chemicals, including therapeutic drugs and some carcinogens as well as some endogenous compounds such as steroids. Genetic polymorphisms are well described for some of the P450 series and influence the metabolism and hence response to drugs, those due to debrisoquine and phenytoin being well described [80,81]. Genetic polymorphism is also recognized at one of the two genetic loci (pNAT) encoding *N*-acetyltransferase [82]. These polymorphisms or variants of pNAT influence the rate of acetylation and therefore detoxification of isoniazid; slow acetylators are at risk of drug-related neuropathy (due to accumulated isoniazid) or hepatitis (thought to be due to production of a toxic isoniazid metabolite via an alternative biochemical pathway) [83]. Therefore these slow acetylators need lower doses of medication to achieve a therapeutic effect and to avoid toxicity. The genetic variants of pNAT can now be recog-

nized by direct and simple polymerase chain reaction (PCR)-based assays and are most commonly found in Asian populations [84].

Generally, however, the response of infections to antibiotics depends more on microbial than on human genetics.

### **Tumour genetics**

The observation that many potent carcinogens are also potent mutagens (DNA-damaging agents) has strongly suggested that malignant transformation of a cell is based on DNA change, or mutation, in the somatic cells (somatic mutation) and that the change is inherited by the population of daughter cancer cells [85]. Cigarette smoke is a particularly powerful mutagen for human cells, containing a great range of chemical mutagens including aromatic hydrocarbons, nitrosamines and pyrrolized amino acids [86].

There is now increasing information on the sites and types of somatic mutation underlying malignancy, ranging from visible chromosomal rearrangements to discrete mutations at well-defined loci [87,88]. Among the latter are oncogenes, genes for cellular growth factors and their receptors, and tumour suppressor genes that encode growth-regulating and growth-retarding factors [89]. The interplay of these different molecular factors, which act in the cell nucleus and cytoplasm, in promoting and controlling cell growth is very complex; however, associations are being defined between certain mutations and disturbance of cell growth and type of tumour. For example, in both small-cell and non-small-cell carcinomas of the bronchus somatic mutations in the gene for P53, an important growth regulator, are well described. Mutations in the cellular oncogene *K-ras* are found in adenocarcinomas of the lung [90].

Germline mutations are also important in influencing risk of developing tumour in a number of ways, for example via pre-existent mutations in an oncogene or variant metabolism of carcinogens. Thus polymorphisms of P4501A1 (which metabolizes polycyclic aromatic hydrocarbons) and P4502E1 (which metabolizes nitrosamines) are associated with increased risk of lung cancer in smokers [91].

### **Microbial genetics**

Respiratory infection causes morbidity and mortality on a worldwide scale: the pneumococcus and *Haemophilus influenzae* are estimated to kill some 5 million children under the age of 5 years in the world annually; the influenza and measles viruses cause numerous epidemics; *Mycobacterium tuberculosis* is the single organism that causes most deaths annually every year; and *Pneumocystis carinii* has been a leading cause of fatal pneumonia in the

severely immunosuppressed, e.g. those with AIDS, and in patients on transplant and oncology treatment programmes. The molecular characteristics of these organisms and others are now being successfully defined and the essential genetic foundations for pathogenicity and response to antimicrobial drugs are being clarified.

In the case of antibiotic resistance, a number of genetic mechanisms have been identified [92].

1 Antibiotic-inactivating enzymes are an important mechanism and involve  $\beta$ -lactams, macrolides and chloramphenicol, e.g.  $\beta$ -lactamase production by *Haemophilus influenzae*; this kind of resistance can be transferred between bacteria by gene transfer on plasmids [93].

2 Change of target is another mechanism, e.g. mutation in bacterial cell-wall peptidoglycans inhibits penicillin binding in *Streptococcus pneumoniae* [94]. Antibiotic resistance in *M. tuberculosis* has been of special interest; in one form of isoniazid resistance, mutations in the *InhA* gene, whose protein mediates mycolic acid metabolism and hence cell-wall structure, result in impaired binding of isoniazid to the target enzyme [95].

3 Another mechanism involves bacterial mutations that limit antibiotic penetration through the cell wall; this is thought to occur in the lipoproteins of the cell wall of *Pseudomonas* species and causes reduced permeability and hence resistance to  $\beta$ -lactams and aminoglycosides [96].

Characterization and cloning of gene sequences from these organisms has important practical aims, and molecular genetic techniques help further in realizing these goals. For example, organism-specific DNA sequences can be used as powerful diagnostic tools whose specificity and sensitivity are impressive when linked to *in vitro* DNA amplification by PCR [97]. Successful PCR diagnostic assays have been developed for a number of pulmonary pathogens, including *Pneumocystis carinii* (Fig. 5.4), and there are indications that a successful method is emerging for tuberculosis [98]. Rapid DNA diagnostics can be also used to identify specified mutations that predict antibiotic resistance [99]. Finally, DNA vaccines may become very effective immunizers for intracellular pathogens such as the influenza virus or *M. tuberculosis*; this is because the chosen microbial DNA is taken up by cells and, following incorporation and expression, is presented 'more naturally' to the immune system on the cell surface by HLA molecules [100].

## Conclusions

Genetic mechanisms play a central role in determining the risk and patterns of lung disease. They act in a great variety of ways, including the inheritance of variants or mutations, the development of mutations in somatic cells and through mutation or transfer of genes in pathogenic microorganisms. The current revolution in molecular biology and genetics is steadily discovering and clarifying these mechanisms and will present great opportunities in the future for improved recognition, prevention and treatment of disease. Finally, the outbred genetics of humans reminds us that patients are truly individual and that clinical medicine, with its scientific content, will continue to be an art.

# CLINICAL ASPECTS

ANTHONY SEATON

The clinical history and examination are fundamental to the assessment of respiratory health even in the epoch of computer-assisted tomography and bronchoalveolar lavage. Indeed, too great an emphasis on the technology of medicine may lead to atrophy of clinical skills and thus loss of judgement in the assessment of an individual's health. No apology is made therefore for including a chapter on basic clinical manifestations.

The patient with respiratory disease is understandably nervous on first consulting a specialist. The main symptoms of respiratory disease are common to a large number of conditions but are likely to be associated in the patient's mind with bronchial carcinoma or tuberculosis. This is especially so if, as is often the case, the patient has been referred on account of a radiological abnormality. Simple matters, like a courteous approach, a friendly smile and sitting patients beside rather than across the desk, help put them at ease and make the history less liable to be coloured by fear or anger. Similarly, the efficiency of the consultation is much enhanced by having basic tests, such as chest radiography and spirometry, carried out before the clinical interview.

Contrary to what the undergraduate may perceive as the proper order, examination of the patient begins as soon as the consultation starts. Especially important is the physician's perception of the patient's non-verbal response to questions; hesitancy or lack of eye contact may indicate that there is more, or less, in an answer than meets the ear. Further questioning following such clues often reveals, for example, that the patient did in fact cough some blood a few weeks ago, or that he has only been a non-smoker for 24 h. Observation of the patient during the questioning usually allows assessment of the patient's mood, which inevitably affects the reaction to whatever symptoms he or she may have, and is particularly important in interpreting subjective symptoms such as dyspnoea.

In taking the history, it is important to remember that most respiratory diseases are acquired or made worse by the inhalation of toxic material. While this is often

obvious, for example in the case of cigarette smoke, common allergens or pathogenic bacteria, sometimes the source of the disease is far from clear. The history should always include questions directed towards environmental factors that may be responsible, such as exposure to dust or fumes and allergens or infective particles, at home or at work. In the case of suspected allergic disease of undetermined cause, examination may include a visit to the home and workplace. A history of drug-taking, generally for medical reasons but increasingly nowadays in drug and alcohol abuse, may be relevant to pulmonary disease.

The course of the history should lead to a narrowing down of the diagnostic possibilities. In addition it should allow the physician to understand how the patient's life differs from that of the fit individual. Since many patients with chronic disease tend to adapt to their condition and regard as normal what others would perceive as disability, it is useful to ask patients to compare themselves functionally with healthy people whom they know. It is also important to build up a picture of how the functional impairment has developed. The simplest way to do this is to take the patient back through landmarks in his or her life, enquiring as to symptoms and illnesses at these times; for example, recurrent illnesses as a child, playing games at school, fitness for military service, chest trouble during pregnancy, and so on. A sequential history of the current illness, with emphasis on its commencement and progression, usually allows differentiation of different diseases, for example asthma from smoking-induced chronic airflow obstruction, because of the typical variability of the former, and breathlessness due to acute pulmonary embolism, laryngeal carcinoma and emphysema, because of the different time-courses of their onset. While these points may seem obvious, the author has seen many cases in which these different conditions have been misdiagnosed, sometimes with unhappy results, because a careful history had not been taken.

At the end of the clinical consultation, and with the help of chest radiographs and lung function tests, the physician should usually know the most likely causes of the

patient's ill-health and be in a position to plan treatment or further investigation. At this stage, the doctor should spend time explaining the position to the patient or, in the case of children or the confused, a relative. A simple statement of the suspected diagnosis, its implications and the planned course of action, with a moment for answering questions, is ideal and the timing of the consultation should be planned with this in view. Each doctor develops a personal method of imparting information about potentially fatal disease; suffice to say that there is no one way of doing this but that attempts to deceive a patient are rarely successful or to the benefit of the patient and the family. An optimistic approach by the doctor towards either the response to curative treatment, if feasible, or palliation of symptoms should be maintained. Equally, in the case of non-fatal disease, it is often important for the doctor to state explicitly that the patient does not have cancer. It should be remembered also that for many older patients the diagnosis of tuberculosis implies at best some years in sanatoria and at worst death, so appropriate reassurance should be given.

## Principal symptoms of respiratory disease

### Cough

Cough is one of the most common reasons for a patient to consult a doctor at all ages [1,2]. Nevertheless, patients with chronic cough, especially when related to cigarette smoking, may become so accustomed to it that they deny they have it, even when they admit to the regular production of sputum. The act of coughing is under voluntary control, although it commonly occurs as a result of an involuntary reflex, and is designed to remove secretions or inhaled particles from the bronchial tree or pharynx. Cough consists of contraction of the respiratory muscles against a closed glottis, with resultant rise in intrathoracic pressure, followed by opening of the glottis and forced expiration with very high flow rates in the upper airways. These rates are increased by the narrowing of the airways that occurs due to invagination of the non-cartilaginous part by the high intrathoracic pressure prior to glottal opening, and can only be sustained momentarily since after glottal opening the airways collapse as in any forced expiration. In patients with severe airflow obstruction, high rates of flow cannot be generated because of the fixed airway narrowing; such patients may have prolonged wheezy coughs that sometimes cause the involuntary effects of a Valsalva manoeuvre and resultant cough syncope. Such episodes may occasionally be accompanied by convulsions that mimic epilepsy [3].

The involuntary initiation of cough takes place through a reflex arc that has its receptors in the respiratory tract [4]. In the mucosa of the larger airways (larynx, trachea and

bronchi) lie rapidly adapting stretch or irritant receptors sensitive to mechanical stimuli. Their principal effect is to initiate a forced expiration without an initial inspiration that would suck inhaled particles further into the lung. Further down the airways, probably as far as the acinus (since cough is a feature of allergic alveolitis and pneumonia), lie receptors sensitive to chemical stimuli, such as the inhalation of irritant gases, which initiate a reflex inspiration and forced expiration. The precise roles of several different receptors identified in the lung, such as C receptors and slowly adapting stretch receptors, in the initiation or suppression of cough have not yet been clearly defined. The efferent messages of the cough reflex travel down the vagus to the larynx and by the spinal nerves to diaphragmatic, thoracic, abdominal and pelvic muscles, all of which contract during a cough [5,6].

Although the receptors may accommodate to repeated stimuli, as in smokers who only cough after their first cigarette of the day, paroxysms of cough may occur when the inspiration prior to cough in turn stimulates the receptors and initiates a vicious circle. The cough reflex becomes less sensitive in the elderly and is lost in anaesthesia and unconsciousness, contributing to the increased danger of aspiration of stomach contents in such circumstances.

Some features of cough are of diagnostic significance. The non-explosive or bovine cough associated with recurrent laryngeal nerve paralysis is easily recognizable, as is the prolonged wheezy cough of the patient with emphysema. Paroxysms of cough without sputum production occur in people with increased airway reactivity and are commonly provoked by attempts at spirometry. They often follow upper respiratory viral infections and persist for some months as the 'reactive airways dysfunction syndrome' (see Chapter 36). A bubbly cough indicates sputum in the larger airways and the likelihood of expectoration. The paroxysms of coughing followed by a prolonged stridulous inspiration characteristic of pertussis is not easily forgotten by those who have heard them, still less by those who have suffered them.

Most acute episodes of cough are caused by respiratory infections, usually viral. However, the common causes of persistent cough differ at different ages. In neonates, cardiac disease and aspiration through congenital fistulae should be excluded. Later in childhood, chronic maxillary sinusitis, asthma, cystic fibrosis and inhaled foreign body are important causes, although viral infections may cause cough lasting for several months associated with increased bronchial reactivity. Psychogenic cough, sometimes related to maternal anxiety, may occur in children and it should not be forgotten that some children may start to smoke at a very young age. In adult life, persistent cough is most commonly related to cigarette smoking. This usually occurs with the first cigarette and does not trouble the patient unless it is exacerbated by infection. A change in the pattern of cough is an important symptom of

bronchial carcinoma. In adult non-smokers, persistent cough is usually due to asthma, though again viral infections may provoke a cough that lasts for some months. Other less common causes are extrinsic allergic alveolitis and humidifier fever. Exposure to dusts and fumes at work is now well recognized as a cause of persistent cough, even in non-smokers. Tuberculosis, bronchiectasis, cystic fibrosis, sinus and laryngeal disease, sarcoidosis, lymphoma, pulmonary fibrosis and pulmonary oedema are other causes of persistent cough. In adults, especially older people, oesophageal reflux is a not uncommon cause, probably based on a reflex, that is often overlooked [7]; all patients with chronic cough of undetermined cause should be investigated with this in mind, especially as it may occur in the absence of symptoms of reflux [8]. Cough may also be caused by recurrent aspiration related to reflux, oesophageal stricture or neurological disease affecting swallowing. Asthma and cardiac failure also commonly cause cough in the elderly; these three latter causes frequently provoke a predominantly nocturnal cough. The use of angiotensin-converting enzyme (ACE) inhibitors in cardiovascular therapy is another cause of cough in older patients [9], perhaps caused by a failure of the normal breakdown of bradykinin by ACE [10]. Fortunately, this occurs much less frequently with the newer angiotensin II inhibitors, which can usually be substituted for the ACE inhibitor if cough is a problem [11,12]. In some cases, no physical cause for cough may be found; in a few of these patients psychogenic factors may be important, although this is a diagnosis that should not be made lightly and without some positive evidence of an appropriate psychological cause.

The management of cough depends on the cause [2]. Since most coughs are transient and related to upper respiratory tract infections it is normally appropriate to treat such a suspected infection and/or to wait for 2–3 weeks before investigating further. The history of course provides clues about the aetiology, helping to exclude such causes as bronchiectasis, aspiration, dust inhalation and allergic factors. Chest radiography and spirometry should be carried out on patients with persistent cough and this may be followed in appropriate cases by bronchoscopy, otorhinological examination, barium swallow, bacteriological investigation and so on. Treatment is then normally that of the cause, although sometimes it may be necessary to suppress the cough. This is most commonly the case with cough due to viral infections, when a paroxysmal non-productive cough becomes a social nuisance, and with bronchial carcinoma, when cough may be an important contributor to the misery of a terminally ill patient (see Chapter 60).

It is not uncommon in respiratory practice to see patients in whom an irritant, unproductive cough persists for months or even years. Such patients, who in the author's experience are more frequently female than male

(and there is evidence that sensitivity of the cough reflex is greater in females [13]), complain of paroxysms of cough, often unprovoked or after laughing, talking or exposure to smells, and commonly give a history of what sounds to have been an initial upper respiratory tract infection. Lung function and chest radiography are normal. The first step in managing these patients is to exclude treatable disease. This includes investigation for sinus disease and oesophageal reflux. If there is any evidence of reflux, it should be treated medically, and this often improves the cough. A test for bronchial hyperreactivity is useful and, if present, a trial of antiasthma medication is worth giving with a fair prospect of success. Indeed, it is reasonable to give such a course without prior methacholine testing and anticipate a 50% success rate. If neither of these measures help, the patient is likely to have increased cough sensitivity, demonstrable by a capsaicin challenge test [14,15]. Such patients are difficult to manage. They should first be reassured that there is no serious disease and told that they have irritable airways. It is the author's practice then to explain that treatment may be unsatisfactory but that there are a number of options, any one of which might help. The aim is to break the vicious circle of cough, airway irritation and more cough. These options include the use of proprietary cough mixtures (paradoxically, those containing small doses of capsaicin such as Fisherman's Friend are often helpful), more powerful cough suppressants and anticholinergic inhalers. The use of small regular doses of codeine linctus, supplemented by steam inhalation and cups of tea, is adequate in many cases. For more severe cough, a course of the potentially addictive methadone linctus may be justified. In some cases, psychogenic factors may seem important (though generally anxiety is secondary to the tiresome cough) and anxiolytic therapy may be tried.

### Sputum

The production of bronchial secretion has been described in Chapter 1. Expecterated secretions are known as sputum or phlegm and examination of this material is an important component of the clinical examination of a patient with chest disease. In enquiring about sputum production, the important points are its volume, timing and colour. In addition, a patient may be able to comment on its consistency and occasionally its smell. Most patients with chronic airways disease produce less than an eggcupful daily, but the volume increases during infective exacerbations. Large volumes are sometimes expectorated in bronchiectasis, when cough may be provoked by postural changes. Volumes in excess of 100 mL daily are arbitrarily defined as bronchorrhoea [16–19]; this condition may occur in many chest diseases for unknown reasons. The author has seen it in asthma and chronic bronchitis as well as in patients with alveolar cell carcinoma. It is also a

feature of acute organophosphate poisoning and may follow ingestion of neurotoxins from eating exotic fish [20,21].

The history of sputum production is important in differential diagnosis. Chronic morning expectoration over years suggests smoking-induced bronchitis; variable morning or nocturnal expectoration suggests asthma; recent onset suggests infection. This information, together with information on the colour and consistency of the sputum, often leads to a working diagnosis. In particular, green or thick yellow sputum usually means infection. The yellow colour and the changed consistency come from the presence of leucocytes. Stagnation of sputum containing leucocytes results in a green colour because of the liberation of the green enzyme verdoperoxidase (or myeloperoxidase) from the cells as they are broken down [22]. While infection is the usual cause of persistently green sputum, it should be noted that the first sputum produced in the morning by many bronchitic subjects may be green because of nocturnal accumulation of leucocytes, while that produced later in the day reverts to a clear colour. Moreover, asthmatic sputum is often heavily laden with eosinophils [23] and these may also give a yellow or green colour to the sputum. Rusty coloured sputum is characteristic of pneumococcal pneumonia. Blood-stained sputum is discussed in the next section. Sputum like anchovy sauce is diagnostic of a ruptured amoebic liver abscess, while treacly black sputum (melanoptysis) results from expectoration of the contents of necrotic massive fibrosis of coal-miners.

Patients often notice the consistency of sputum, though they may find it difficult to describe. In general, sticky sputum that is difficult to expectorate occurs in infection and bronchial asthma. As the condition responds to treatment, the sputum becomes looser and more easily produced. An important indication of recovery from an acute attack of asthma is the ability to expectorate [24]. Often in these circumstances, the patient coughs up worm-like structures that are casts of bronchi and that histologically consist of eosinophils, desquamated epithelium, Curschmann's spirals (curious spiral arrangements of eosinophils) and Charcot-Leyden crystals [25]. Such bronchial casts are also a feature of the sputum of some patients with allergic bronchopulmonary aspergillosis [26]. Rarely, expectoration of intrabronchial tumour may occur; this is particularly characteristic of metastatic renal carcinoma [27]. Important clinical information may occasionally be obtained from the smell of sputum. Anaerobic infection may produce a very offensive smell, characteristically occurring in some patients with bronchiectasis and lung abscess. Gram-negative organisms also may impart a distinctive odour to sputum, similar to that of *Escherichia coli* on a culture medium. These odours may be used as a guide to initial antibiotic treatment while awaiting bacteriological results.

In spite of much study of the biochemistry and rheology of sputum, little has been learned that is of practical value to the clinician. The worthwhile investigations of sputum, apart from the observations described above, are microscopy for bacteria, malignant cells and occasionally other microorganisms, culture for bacteria, and tests for pneumococcal antigen. Culture for fungi may be misleading, as these organisms are commonly inhaled from the aerospora and are of no pathogenic importance. However, microscopy for fungal hyphae is important when fungal infection is suspected [28]. Differentiation of sputum from saliva can be made by microscopic observation of alveolar macrophages, while differentiation from gastric contents can be made by testing for pH. Specimens of sputum for bacteriology or cytology are best obtained first thing in the morning by a deep cough, if necessary stimulated by steam inhalation or ultrasonically nebulized saline.

Management of sputum production depends on treatment of the primary condition. In patients with asthma the cough may be useful (productive of sputum) or a nuisance [29] and, if the latter, usually responds to bronchodilators. Except in terminally ill patients it is unwise to suppress a productive cough, although this may occasionally be necessary to allow a distressed patient some rest. Green sputum is usually an indication for antibiotics, or occasionally antiasthmatic drugs, whereas clear mucoid sputum in the presence of pulmonary infection suggests that antibiotics should, in the first instance, be those active against *Mycoplasma pneumoniae* and similar organisms. Bronchorrhoea is often difficult to control. If a primary cause cannot be found and treated, prednisolone 40 mg daily for a week may produce improvement. Erythromycin has also been used with success in some cases associated with alveolar cell carcinoma and would seem to be worth a trial [30]. Fluid restriction and anticholinergic drugs may be tried though they are often unsuccessful and the unfortunate patient may have to put up with the symptom. In idiopathic cases, spontaneous remission may occur.

### Haemoptysis

Blood-stained sputum should be differentiated from bleeding in the mouth or pharynx and from haematemesis. Usually, but not always, this can be ascertained from the history. Haemoptysis is rarely a solitary event, almost always being followed by the production of further blood-stained sputum. Although it is a symptom that should always be taken seriously, in approximately one-third of cases no obvious cause can be found.

The most common causes of haemoptysis in respiratory practice are bronchial carcinoma, pulmonary infarction, tracheitis, tuberculosis, bronchiectasis, pneumonia (especially pneumococcal) and trauma. Less common, but important, causes are cystic fibrosis, mitral valve disease,

haemosiderosis and Goodpasture's syndrome, aspergilloma, inhaled foreign body, arteriovenous malformations and primary haemorrhagic diseases. Blood-tinged sputum also occurs in acute left ventricular failure. Often, when none of the above causes is found haemoptysis may be ascribed to chronic bronchitis, usually associated with an acute infective exacerbation, or systemic hypertension. It is always important to exclude a source of bleeding in the upper respiratory tract, especially from tumours of the pharynx or larynx.

A chest radiograph is mandatory in anyone with haemoptysis and often shows a lesion. In adults over 40 and in smokers, bronchoscopy is usually advisable unless a non-malignant cause is obvious [31]. It should also be carried out in other individuals in whom the haemoptysis recurs after an interval of observation. Sputum cytology may be worth carrying out in patients with recurrent haemoptysis and normal bronchoscopy, as this symptom may be the first evidence of a very early bronchial tumour. Finding malignant cells in the sputum of such patients does of course raise considerable problems in further investigation. Examination of the sputum may also reveal iron-containing macrophages in patients with haemosiderosis and Goodpasture's syndrome. Other special investigations may include bronchography, pulmonary or bronchial arteriography [32] or ventilation-perfusion scanning (see Chapters 7 & 8).

The management of haemoptysis depends on the primary condition. Even massive haemoptysis is rarely fatal though it certainly can be, particularly when coming from bronchial arteries in aspergillomata and tuberculous cavities, or following iatrogenic trauma to vascular tumours with biopsy forceps or to fibrotic lung with drill or needle. Dramatic, fatal haemoptysis may also result from rupture of aortic or even pulmonary artery aneurysms. In general, haemoptysis settles if the patient is rested and sedated. Radiotherapy is often successful in stopping bleeding from bronchial tumours, while other local causes of persistent haemorrhage may sometimes be controlled by bronchial artery embolization [33,34]. Bleeding from aspergilloma may be controlled by radiotherapy or intracavitary instillation of antifungal drugs [35]. The fatal consequences of severe, massive haemorrhage may be postponed by assisted ventilation and transfusion while awaiting the assistance of the thoracic surgeon.

### Chest pain

Pain in the chest may derive from the chest wall, the pleura, the trachea and main airways or the mediastinal and abdominal structures. Cardiac pain and oesophageal pain are common and need to be considered in the differential diagnosis of a patient presenting to the respiratory physician with chest pain. Some of the important causes of chest pain are given in Table 6.1. The diagnosis of chest

**Table 6.1** Some causes of chest pain.

<i>Chest wall pain</i>
Persistent cough or breathlessness
Muscular strains
Intercostal myositis
Thoracic herpes zoster
Coxsackie B infection
Thoracic disc lesion or nerve compression
Intercostal nerve compression or infiltration

Rib tumour: primary or metastatic
Tietze's syndrome
Slipping rib syndrome
<i>Pleural pain</i>
Infective pleurisy
Pneumothorax
Autoimmune disease
Asbestos pleural fibrosis
Mesothelioma
Metastatic tumour
<i>Airway pain</i>
Tracheitis
Inhalation of irritant gas
Intubation
Central bronchial carcinoma
<i>Mediastinal pain</i>
Cardiac ischaemia/infarction
Massive pulmonary embolism
Oesophagitis
Pericarditis
Sarcoid adenopathy
Lymphoma
Mediastinitis
Aortic dissection
Aortic aneurysm

pain is largely dependent on an ability to take a careful history. The mode of onset, length of time, site and radiation, relationship to movements and breathing, and severity are all important points to enquire about. Specific causes of pain are dealt with in appropriate chapters of this book, but a few general points are made here.

Many patients with chronic breathlessness, caused for example by asthma or emphysema, admit to rather generalized chest pains when asked directly, and in some it is a presenting symptom. This is usually over the lower lateral parts of the chest and related to breathing and coughing. It is rarely severe enough to be the main complaint. More severe generalized chest wall pain occurs in Bornholm disease (Coxsackie B virus infection) and in some collagen diseases such as polymyalgia rheumatica and dermatomyositis. Localized chest pain is frequently due to muscle strain related to persistent cough or unusual exertion and associated with local tenderness and pain on movement, although a similar symptom is often expressed by people with diffuse pleural fibrosis caused by asbestos. Pain in

the distribution of a spinal nerve should always raise the suspicion of prevesicular herpes zoster; the spine should be examined carefully and a spinal radiograph taken. Tumours of the spinal canal are sometimes referred initially to chest clinics, though osteoporotic and malignant vertebral collapse are more common causes of this syndrome. Localized rib pain associated with tenderness usually denotes a fracture, which may be due to coughing bouts in the elderly or to osteoporosis. If so, the rib involved is usually around the seventh. Pain that keeps a patient awake is always to be regarded as organic and is often of sinister import. Rib tumours, infiltration of intercostal nerves by carcinoma (as in the Pancoast syndrome) and mesothelioma, and compression of spinal nerves are important causes of such pain.

Central anterior chest pain is usually related to either cardiac ischaemia or oesophagitis. However, occasionally disease of other mediastinal structures may be responsible. The most frequent is tracheitis, which causes a burning pain related to inspiration. A central carcinoma sometimes causes a dull ache, occasionally referred to the lateral chest wall over the involved lobe. Enlarged mediastinal nodes due to sarcoidosis or lymphoma sometimes cause anterior chest pain that may be severe, although more usually they are symptomless. Pain associated with retrosternal goitre or thymoma suggests that the lesion has become malignant.

Pleuritic chest pain is discussed further in Chapter 43. It occurs on inspiration and disappears when an effusion appears. If the central diaphragmatic pleura is involved, it is referred to the shoulder-tip as the sensory fibres run up the phrenic nerve (C3,4). Pleurisy can be mimicked exactly by Bornholm disease.

### Breathlessness

Shortness of breath is one of the commonest reasons for referral of a patient to a chest clinic. The clinical approach to this symptom has been little influenced by the considerable amount of physiological research that has gone into explaining the sensation of dyspnoea, nor does it pay much attention to the nice distinctions between dyspnoea, tachypnoea, hyperpnoea and hyperventilation. A simple but useful clinical approach considers breathlessness as due to cardiac, respiratory or other causes (Table 6.2). The history, with special emphasis on the mode of onset, timing, progression and severity of the symptom, normally allows its tentative ascription to one of these causes. Cardiac dyspnoea is usually progressive, first noticed on exertion, often associated with orthopnoea and sometimes with paroxysmal nocturnal dyspnoea. Examination of the patient's cardiovascular system and ECG usually reveals diagnostic abnormalities. Non-cardiorespiratory causes of breathlessness are relatively uncommon. The most frequent one seen in chest clinics is related to psychogenic

**Table 6.2** Some causes of breathlessness.

<i>Cardiac</i>
Left ventricular failure
Mitral valve disease
Cardiomyopathy
Pericardial effusion or constriction
<i>Non-cardiorespiratory</i>
Psychogenic
Anaemia
Haemorrhage
Acidosis

<i>Respiratory</i>
Airways disease
Chronic bronchiolitis and emphysema
Asthma
Bronchiectasis and cystic fibrosis
Laryngeal or pharyngeal tumour
Bilateral cord palsy
Cricoarytenoid rheumatoid
Tracheal obstruction
Tracheomalacia
Amyloid of airways
Parenchymal disease
Allergic alveolitis
Sarcoidosis
Fibroses and diffuse alveolitis
Obliterative bronchiolitis
Pneumonias and toxic pneumonitis
Diffuse infections
Respiratory distress syndrome
Infiltrative and metastatic tumour
Pneumothorax
Pulmonary circulation
Pulmonary embolism and hypertension
Pulmonary arteritis and thrombosis
Chest wall and pleura
Effusion or pleural fibrosis
Fractured ribs
Ankylosing spondylitis
Kyphoscoliosis
Neuromuscular, bilateral diaphragm paralysis

factors. The patient often complains of shortness of breath while resting more than on exertion, and of the need to take a deep breath or the sensation of being unable to take a full breath. Exercise tolerance is often unimpaired. In extreme cases the patient overcompensates by hyperventilating, causing dizziness, lightheadedness, tingling in the fingers and even tetany or syncope. There are often associated features of anxiety or depression and the patient is usually a rather introspective or obsessive individual. The syndrome tends to occur in younger people and is not uncommon in unsophisticated and over-coached athletes. Other non-cardiorespiratory causes of breathlessness are

rare. They include anaemia, haemorrhage and intracranial lesions.

Respiratory causes of breathlessness may be divided into those due to disease of the airways, the lung parenchyma, the pulmonary circulation and the pleura and chest wall. Airway diseases usually cause a pattern of airflow obstruction; asthma, chronic bronchiolitis and emphysema are the usual causes of this. The former typically causes a history of intermittent and variable breathlessness, with nocturnal episodes. As the disease progresses untreated it may become less variable, but a good history will reveal variability over the initial years. Chronic airflow obstruction due to smoking is typically of insidious onset with little variability and remorseless progression. It only rarely starts after the individual has stopped smoking, an important point in differentiation from asthma which not infrequently presents for the first time in an ex-smoker. Less common than the above two causes of airflow obstruction is that due to obstruction at the larynx or pharynx, usually by tumour. Here the patient may complain of noisy or wheezy breathing, as in asthma, but the history is short and progressive over a few weeks or months. It may be worse on lying down. Obstruction of the trachea by tumour causes a similar type of breathlessness, while obstruction of a main bronchus leading to collapse of a lung or lobe usually causes rather rapid onset of dyspnoea to which the patient may partially adapt quite quickly. This is the one airway disease not associated with an obstructive pattern on lung function testing. Less common causes of breathlessness due to airflow obstruction include bronchiectasis, cystic fibrosis and diffuse airway diseases such as amyloidosis and tracheomalacia. Inhalation of toxic liquids or fumes may also lead to permanent airflow obstruction.

Diseases that affect the lung parenchyma usually cause a steadily progressive type of breathlessness with a restrictive pattern of lung function. Moreover, they are often associated with clinical signs and radiological appearances that make their diagnosis relatively straightforward. Diffuse infiltrative diseases include sarcoidosis, various forms of alveolitis and fibrosis, alveolar cell and metastatic carcinoma (carcinomatous lymphangitis causes particularly marked and intractable breathlessness) and diffuse infections with organisms such as *Pneumocystis carinii* and *Cryptococcus neoformans*, as seen increasingly since the arrival of AIDS. Allergic alveolitis may cause a slowly progressive dyspnoea, although commonly there is variability in symptoms and improvement with avoidance of the antigen. Simple pneumothorax, of course, causes chest pain and breathlessness of sudden onset with subsequent amelioration, while tension pneumothorax causes steadily progressive and ultimately severe breathlessness leading to a medical emergency.

Diseases of the pulmonary circulation, such as arteritis or primary pulmonary hypertension, cause a progressive

dyspnoea often with very severe exercise limitation in the later stages. Pulmonary embolism usually causes acute dyspnoea of very sudden onset, while multiple small emboli can mimic primary pulmonary hypertension. Pulmonary arterial thrombosis is sometimes responsible for acute worsening of dyspnoea in an already disabled patient with chronic airflow obstruction and polycythaemia.

A variety of chest wall diseases may cause breathlessness. Kyphoscoliosis, if severe and situated in upper or mid-dorsal spine, may lead to cor pulmonale in the 30–40-year age group. Ankylosing spondylitis may also cause severe restriction and breathlessness even in the absence of the accompanying pulmonary fibrosis. Motoneurone disease, poliomyelitis and some muscular dystrophies may cause breathlessness and respiratory failure. Bilateral diaphragmatic paralysis is an uncommon but easily missed cause of breathlessness. When the patient lies down, paradoxical movement of the abdomen with respiration may be observed.

There has been much debate about the mechanisms of dyspnoea [36,37]. It is reasonable to suppose that different mechanisms are responsible in different situations, for example the sensations in asthma of difficult inspiration and uncomfortably overfilled lungs are probably quite different to those in left ventricular failure or psychogenic breathlessness. All have in common the impingement on the consciousness of a normally subconscious process. This is even true of the normal breathlessness at extremes (for an individual) of exertion. The sensory limb of the neural control of respiration is from receptors in lung and respiratory muscles via the vagus and spinal nerves to the respiratory centres in the brainstem and sensory cortex. The motor limb is also under both cortical and brainstem control. Some of the reflexes involved in respiratory control have been described in Chapter 2. One concept of dyspnoea suggests that it results when there is disturbance in the relationship between the force applied to the lung and the movement to which it gives rise, so that the resulting ventilation does not equate with the demand of the respiratory centres [38,39]. This theory of length-tension inappropriateness holds that subconscious comparison is constantly being made between ventilation and activity, between ventilation demanded and ventilation achieved, and between muscle tension exerted and change in muscle length achieved. When the inappropriateness of these relationships exceeds a certain threshold, the sensation of the need to breathe more deeply or rapidly reaches consciousness. This sensation may arise in the respiratory muscle spindle, although the diaphragm appears to be somewhat deficient in these structures [40].

It is useful clinically to record the severity of breathlessness in terms of restriction of a patient's activity. This is usually best done for milder degrees by comparison with healthy members of family or friends. In more severe

breathlessness, the length of time taken to do certain tasks, like shaving, dressing or getting down to breakfast, is a useful indicator. The length of time to walk known distances has found application in a simple test of lung function [41] (see Chapter 2). Grading of breathlessness on a scale, such as those designed by the Medical Research Council [42] and Davis *et al.* [43], is of value in research and particularly in epidemiology but tends to be confusing clinically as different doctors use different scales. Table 6.3 shows these two best-known scales, the one designed for use in the epidemiological study of chronic chest disease and the other for research in patients hospitalized with acute severe asthma. The different applications of these two are implicit in the questions; the Jones scale is of severe dyspnoea from grade 2a upwards while grade 1 is roughly equivalent to the most severe grade of the MRC scale, which of course was designed for use on ambulant populations. Others studying the mechanisms of dyspnoea on exercise use the 10-point Borg scale, 1 and 2 being slight and 9 and 10 severe [44].

The management of dyspnoea, as of other respiratory symptoms, depends on determining and treating the cause. It is unfortunately true that if the cause cannot be removed there is often little that can be done to relieve the symptom. This situation occurs distressingly frequently in respiratory practice, particularly in emphysema, pulmonary fibroses and neoplastic bronchial obstruction and pulmonary infiltration. In terminal disease, opiates and antidepressants are helpful. In other conditions, aids in the house, walking aids and wheelchairs may be of assistance and oxygen may be used for temporary relief of acute breathlessness. The use of long-term oxygen is discussed in Chapter 24. The patient with chronic airways obstruction can show benefit from a fitness-training programme [45] and this may also be a considerable morale-booster. The breathless patient often suffers more from loneliness

due to immobility and isolation than from the dyspnoea and any measures to help in this direction are of great value. The sensation of dyspnoea may be affected by centrally acting drugs such as diazepam as well as opiates, and it is possible that in the future drugs acting on the peripheral receptor mediators may be found useful. Indomethacin, the prostaglandin inhibitor, has been shown to alter dyspnoea on exercise in normal subjects [46]. Any of these drugs might justifiably be tried in the emphysematous patient distressed by dyspnoea.

## Signs of respiratory disease

### General observations

#### Pattern of breathing

The most important general observations made by the chest physician relate to the patient's breathing and psychological state. Clearly, one affects the other and skilful management of the patient depends on a proper assessment of both. The physician should observe the patient's breathing during the interview and while undressing for the examination. Moreover, if a patient complains of breathlessness on exertion, it is as sensible to observe the breathing pattern during mild exercise on stairs or along a corridor as it is to examine the nose of someone complaining of rhinitis. This is especially important if the patient is being considered for thoracic surgery.

In the clinic a number of different types of breathing may be observed. Noisy inspiration denotes narrowing in large airways, usually due to asthma or chronic bronchitis though occasionally a tracheal, pharyngeal or laryngeal tumour may be responsible. The noise of breathing is generated by turbulent flow in the large airways, where rates of flow are sufficient to generate it. The noise consists of the whole range of audible frequencies and is sometimes called white noise by analogy with white light [47]. Rapid flow rates through normal large airways, as on exercise, generate greater turbulence and therefore more noise. However, noise during quiet breathing is always a sign of disease of the larger air passages. With severe obstruction of these passages, the noise takes on the characteristics of stridor, a high-pitched musical note on inspiration (and in very severe obstruction also on expiration). This sound is familiar to most parents of young children as croup. In adults it usually denotes carcinomatous narrowing, although intrinsic laryngeal disease (e.g. caused by rheumatoid disease and vocal cord palsies) and tracheal narrowing due to lymph nodes, granulomata, aortic aneurysm or cylindroma may be responsible. Occasionally stridor is a feature of severe attacks of asthma with anaphylactic features; it can also occur sometimes during hysterical hyperventilation. Some causes are shown in Table 6.4. The musical note of stridor is generated by

**Table 6.3** Classifications of breathlessness.

#### *After Medical Research Council*

- Grade 1: troubled by shortness of breath when hurrying on level ground or walking up a slight hill
- Grade 2: short of breath when walking with people of own age on level ground
- Grade 3: have to stop for breath when walking at own pace on level ground

#### *After Sherwood Jones [43]*

- Grade 1a: able to do housework or job with moderate difficulty
- Grade 1b: carrying out job or housework with great difficulty
- Grade 2a: confined to chair or bed but able to get up with moderate difficulty
- Grade 2b: confined to chair or bed and only able to get up with great difficulty
- Grade 3: totally confined to chair or bed
- Grade 4: moribund

**Table 6.4** Some causes of stridor.

Anaphylaxis
Toxic gas inhalation
Inhaled foreign body

vibration of the airway walls when those airways are close to closure, while the pitch is related to the rate of airflow. Stridor occurs predominantly on inspiration because extrathoracic air passages are reduced in diameter when air is drawn into them, owing to the relatively negative pressure engendered (the Bernoulli effect). With abnormal narrowing of these airways acceleration of airflow occurs, which causes a further drop in pressure due to this effect [48].

Wheezy breathing is often audible to the unaided ear and is evidence of intrathoracic airways narrowing; this is discussed further in the section on auscultation (see p. 114). Relatively quiet breathing accompanied by pursing of the lips on expiration is characteristic of pure emphysema, where the airways narrow only on expiration because of loss of elastic recoil. It seems likely that pursing of the lips increases the pressure during expiration, thus reducing the extreme degree of airways collapse that occurs in these patients [49]. It has also been shown to have important mechanical effects on the respiratory muscles that results in protection of the diaphragm from fatigue and improvements in arterial oxygen saturation [50]. Irregular breathing interspersed with sighs is characteristic of psychogenic dyspnoea.

In the hospital setting, other forms of breathing may be observed; the characteristics of breathing during sleep are the subject of Chapter 47. The respiratory rate at rest while awake, faithfully if unnecessarily recorded by nurses from the days of the pneumonic crisis, is normally about 15/min. Slow breathing may be seen in myxoedema, raised intracranial pressure and with hypothalamic lesions. Rapid breathing occurs with lobar pneumonia, pulmonary oedema, pulmonary embolism and pulmonary fibroses, as well as in anxiety. Cheyne-Stokes breathing, or periodic respiration, is a condition of increas-

ing rate and volume of respiration followed by a period of apnoea or hypopnoea. It is seen most frequently in patients with raised intracranial pressure and after sedative drug overdoses, but in a less dramatic form occurs in sleep and in cardiac failure. It seems to be related to a delay in circulation time between the lung and the chemoreceptors [51,52], together with probable altered sensitivity of the respiratory centres to chemical control. It is noteworthy that the  $P_{CO_2}$  is low even during the phase of hypopnoea and that the respiratory response to carbon dioxide is increased [52,53]. Finally, hyperventilation with deep, sighing respirations (Kussmaul breathing) is a well-known physiological response to metabolic acidosis, as in renal failure, salicylate or methyl alcohol poisoning or as a side-effect of treatment with phenformin. This is the one manifestation of increased ventilation in which the patient may deny breathlessness.

### Cyanosis

Cyanosis is an abnormal blue coloration of skin and mucous membranes, generally due to arterial hypoxaemia though occasionally caused by methaemoglobinaemia or sulphhaemoglobinaemia. It is often difficult to appreciate in artificial light unless quite gross, and is best seen on the lips and under the tongue [54]. In good conditions it is detectable when oxygen saturation of arterial blood drops to about 87% but is a sign subject to considerable observer variability. It can easily be missed in a careless examination of a vasoconstricted patient and is less prominent in severe anaemia, since it is dependent on the amount of reduced haemoglobin. Conversely, it is frequently present but not necessarily of clinical significance in polycythaemia.

### Appearance of the chest wall

The chest wall may look abnormal or may move abnormally. Overinflation, where there is an increased antero-posterior diameter, is often accompanied by reduction in the length of trachea above the suprasternal notch and increased prominence and activity of sternomastoid muscles. In such circumstances, the normal lateral and outwards (bucket handle) movement of the ribs is lost, the thoracic cage being pulled up solely by the anterior and upwards (pump handle) movement of the ribs. Sometimes indrawing of the lower ribs and intercostal spaces on inspiration may be seen due to contraction of a flattened diaphragm. Fibrosis or collapse of upper lobes, or severe pleural thickening, may cause flattening of the chest wall anteriorly and diminished respiratory excursion. Long-standing disease on one side may be the cause of a mild scoliosis.

Two common deformities, pectus excavatum (funnel chest) and pectus carinatum (pigeon chest), do not cause

respiratory problems though both may cause social embarrassment sufficient to justify corrective surgery. Pectus carinatum was often the sequel to poorly controlled childhood asthma. In contrast, kyphoscoliosis, if severe and situated primarily in the mid or upper dorsal spine, does lead to respiratory failure in early and middle adult life (see Chapter 45).

Occasionally, other important clinical clues may be apparent on inspection of the chest. A prominent sternomastoid muscle on one side indicates a deviated trachea. Scars of previous thoracotomy, phrenic nerve crush or scalene biopsy should be noted. Rarely, a rib tumour, direct spread of pleural tumour, diffuse metastases or even aortic aneurysm present as swellings on the chest wall. Neurofibromata and spider naevi are other lesions that may indicate general disease with effects on the respiratory system.

### Clubbing and hypertrophic osteoarthropathy

Finger (and toe) clubbing is clearly present when the normal angle between the proximal part of the nail and the distal skin over the nail bed is lost [55–60] (Fig. 6.1). At the same time it may be possible to convince oneself that the nail bed is more fluctuant than usual. As the condition progresses, the whole terminal phalanx becomes swollen and appears like a drumstick. Equally clearly, clubbing is not present when the terminal phalanx looks normal. Difficulty arises when the finger looks somewhere in between; this may be a normal variation or an early stage of clubbing. Not surprisingly there is considerable observer variability when indefinite clubbing is present, and the clinical significance of this sign is correspondingly small. Acknowledgement of this fact is made in Dr Gerald Anderson's half-jocular definition that clubbing is present when three physicians say it is. A simple classification is to divide clubbing into definite, doubtful and absent. In doubtful cases, a tracing round the end of a finger can be put in the notes for future comparison. In any scientific study of the condition, it is necessary to define it more

carefully, and various measurements have been used [61,62]. A relatively simple one sums the ratios of the circumferences of the 10 fingers at the nail bed and at the terminal interphalangeal joint, a 'digital index' that is normally below 10. Confusion sometimes occurs when the ends of the fingers have been subjected to trauma or partial amputations. Hyperparathyroidism and psoriatic arthritis with absorption of terminal phalanges and acroosteolysis due to vinyl chloride exposure may also be confused with clubbing. Clubbing due to any cause may progress to hypertrophic pulmonary osteoarthropathy (HPOA), although this condition is almost always associated with bronchial carcinoma, usually of squamous differentiation. The patient often complains of pain and stiffness about the wrists and ankles and oedema or boggy swelling is sometimes present. Clubbing is usually well marked, although occasionally it may be absent when all other features are present. The diagnosis is confirmed by radiographs, not so much of the wrists and ankles as of the distal forearm and lower leg (Fig. 6.2). The films show subperiosteal calcification separate from the cortex of the long bones.

The patient with HPOA may also have gynaecomastia and rarely thickening and swelling of the end of the nose. While there are very many diseases in which clubbing has been described, the condition occurs most commonly in respiratory conditions associated with hypoxaemia, supuration or neoplasia. Some of the associated diseases are listed in Table 6.5. In the absence of clinical evidence of other disease, it is always wise to assume that the cause may be a bronchial carcinoma and to carry out a chest radiograph. Questioning the patient about the length of time the sign has been present is a curiously unrewarding exercise; even when quite marked changes must have developed relatively recently, patients rarely seem to have noticed them. Congenital and familial clubbing do occur and may lead to HPOA. In one such patient, further investigation was forestalled when his wife (a nurse) confirmed his story that she had insisted that he had a chest radiograph before she agreed to marry him 30 years

**Fig. 6.1** Clubbing of the fingers showing swelling of the nail beds and increased curvature of the nails.

**Fig. 6.2** Severe degree of hypertrophic pulmonary osteoarthropathy showing subperiosteal new bone formation on tibia and fibula.

previously because she had noticed his marked clubbing at that time. The causes of clubbing and HPOA are not known but the following theories have been put forward.

**1 Neurogenic theory.** In this theory it is suggested that afferent impulses from a focus of pulmonary or pleural disease travel via intercostal nerves or vagi to the brainstem and initiate reflex vasodilatation in nail bed and peripheral limb tissues. While no effector mechanism, whether hormonal or neural, has been described, vagotomy or intercostal nerve section does occasionally relieve the symptoms and signs of HPOA [56,57]. On the other hand, most thoracic surgeons are aware that such an operation may be unsuccessful.

**2 Hormonal theory.** This theory suggests that the tumour or diseased pulmonary tissue secretes a hormone that acts on the distal limb tissues. This receives support from the frequently made observation that resection of tumour results in relief of symptoms when the patient wakes from anaesthesia and regression of clinical signs often within a matter of days. Raised oestrogen levels have been found in men

**Table 6.5** Some causes of clubbing and hypertrophic osteoarthropathy.

Bacterial endocarditis
Atrial myxoma

Note: Clubbing is not a usual feature of sarcoidosis, extrinsic allergic alveolitis, coal-workers' pneumoconiosis or silicosis, nor of uncomplicated chronic bronchitis and emphysema.

with HPOA prior to lung surgery, but it is rather unlikely that these are responsible [58].

**3 Shunt theory.** This theory proposes that substances normally degraded on passage through the lungs pass through them via arteriovenous shunts and then act on the tissues of the limb.

The evidence for each of these theories is insubstantial and it is unlikely that there is any one cause for the association of clubbing and HPOA with a wide variety of conditions. Certainly shunts are a feature of a number of them, such as congenital septal defects, arteriovenous malformations and possibly, via increased bronchial circulation, chronic pulmonary suppuration, idiopathic pulmonary fibrosis and bronchiectasis. On the other hand, there is unlikely to be an important increase in shunt with bronchial and pleural tumours, especially as HPOA seems to be associated with the rather less vascular tumours. Here, the secretion by tumour cells of a hormone seems a realistic possibility. All theories require an agent that acts

on the vascular system of the peripheries, causing vasodilatation possibly of arteriovenous anastomoses. There is evidence that the vascularity of the nail bed is not increased as a result of formation of new blood vessels, suggesting that vasodilatation is the common factor [63]. Many possible vasodilators have been proposed, reflecting the medical fashions of the time. Earlier suggestions included oestrogens [58] and ferritin [64], while more recently growth hormone [65], levels of which appear to be higher in patients with clubbing than in those without, and platelet-derived growth factors [66] have become popular. It is of interest that a high proportion of patients being treated for liver disease with prostaglandin E develop finger clubbing and changes of early HPOA [67].

The relief of the symptoms of HPOA is best achieved by removal of the primary tumour. If this is not possible, radiotherapy or chemotherapy may be effective. Anti-inflammatory drugs such as indomethacin and other inhibitors of prostaglandin synthetase are well worth trying if other measures are impossible, and often provide good symptomatic relief. Occasional case reports suggest other drugs may have been of value in difficult cases, for example painful gynaecomastia may respond to tamoxifen and severely painful HPOA has responded to the hormone inhibitor octreotide [68].

### Tremors

The commonest tremor seen in respiratory patients is a fine finger tremor similar to that of hyperthyroidism. It is caused by excessive sympathetic activity due to bronchodilator drugs. Flapping tremor, known to all medical students as a diagnostic feature of hepatic encephalopathy, is seen much more often by the practising doctor in hypercapnic respiratory failure, where it accompanies confusion and electroencephalographic changes as a response to raised intracranial pressure; this in turn is due to cerebral vasodilatation resulting from an acute rise in  $\text{PaCO}_2$  [69].

### Jugular pulse and the superior vena cava syndrome

Apart from its well-known use in the interpretation of an irregular or rapid pulse, inspection of the jugular pulse has several important applications in thoracic medicine. In order to inspect it properly, the physician should move the patient into an appropriate position and light. Absence of pulsation and a persistently raised pressure indicates superior vena caval obstruction (Fig. 6.3). Many dilated venules are usually seen above the rib cage and the face and arms may be swollen and oedematous. The patient often complains of a full feeling in the face and there may be conjunctival reddening and oedema and proptosis. Care should be taken not to misinterpret a kinked external

**Fig. 6.3** The swollen face and neck of superior vena caval obstruction. The jugular veins are engorged and there are dilated chest wall vessels.

jugular vein as superior caval obstruction. The usual cause in the middle-aged and elderly is bronchial carcinoma, often of right upper lobe, with infiltration of the mediastinum, but in younger people lymphoma is more common. Thymoma and thyroid tumours are uncommon causes. Non-malignant causes include fibrosing mediastinitis, thrombosis secondary to a pacemaker wire and, very rarely nowadays, aortic aneurysm.

The diagnosis of the pathological cause of superior vena caval obstruction may pose a problem, as mediastinoscopy and bronchial biopsy may be hazardous because of the risk of bleeding. CT scanning and digital subtraction superior cavagrams are helpful in defining the extent of the lesion and indicate whether intraluminal or extraluminal obstruction is present. In occasional cases, scalene node biopsy may give the diagnosis, and ultrasound-guided transthoracic needle biopsy has been used by some investigators with good diagnostic yield [70]. In most cases it is reasonable to treat the obstruction with

radiotherapy, unless there is some indication that the cause is not a bronchial carcinoma. If biopsy proves possible and the cause is lymphoma or oat cell carcinoma, chemotherapy may give the best chance of inducing remission [71,72]. If recent thrombosis is thought to be the cause, intraluminal injection of thrombolytic agents has been used [73]; if the obstruction does not respond or is due to an untreatable cause, percutaneous insertion of a stent may give good relief of symptoms [74,75].

Pericardial effusions (which occur most frequently as a complication of bronchial carcinoma and tuberculosis) and constrictive pericarditis (which may occur with tuberculosis, rheumatoid disease and mesothelioma) cause the classical signs of elevated jugular pressure, steep 'y' descent and inspiratory rise (Kussmaul's sign). A paradoxical fall in systolic pressure, *pulsus paradoxus*, occurs during inspiration. It is worth noting that this also occurs in acute severe asthma (see Chapter 34), while all the signs of cardiac tamponade may occur in severe congestive heart failure and constrictive cardiomyopathies. Fortunately, ultrasonic investigation makes the insertion of a needle for pericardial aspiration less nerve-racking than it used to be.

### Palpation

Two important pieces of information may be obtained by palpation of the chest. The first is the position of the mediastinum. Upper mediastinal deviation is often accompanied by deviation of the trachea; this should be ascertained by placing the index finger directly into the suprasternal notch and noting which side of the trachea it touches first. As with most physical signs, minor deviations from normal are associated with wide interobserver variability and should only be interpreted in conjunction with other consistent signs. Deviation of the apex beat, along with consistent shift of cardiac dullness, may be an indication of shift of the lower mediastinum. These signs usually accompany other clear evidence of, for example, pulmonary collapse, effusion or tension pneumothorax.

The second piece of evidence concerns movements of the chest wall. These are often more easily felt than seen. It is important when palpating movements to feel them first during quiet breathing. Subtle reduction or delay in expansion, say of an upper lobe whose bronchus is partly blocked by tumour, may be detected quite easily on normal respiration but deep breathing may overcome the obstruction by increasing intrathoracic negative pressure and allowing the lobe to expand normally. While diminished movements may frequently accompany gross and easily detectable collapse, effusion and pneumothorax, the sign is more important as an indication of this incomplete bronchial obstruction where other signs are subtle and also easily missed (the other important one being diminished breath sounds over the involved lobe). An

extreme degree of this syndrome is seen in obstructive emphysema, although it should be stressed that partial degrees, usually with some loss of lobar volume, are much more common. In these cases, the chest radiograph is often apparently normal, the tumour being quite proximal, and if the signs are missed so also may be the opportunity for cure.

Detection of diminished movement largely depends on comparison of one side with the other, and apart from the above may be caused by unilateral fibrosis or bullous emphysema. Symmetrical loss of movement, as with bilateral upper lobe fibrosis, may be inferred if there are other consistent signs, such as flattening of the anterior chest wall and diminished breath sounds.

### Percussion

The technique of percussion was introduced by Leopold Auenbrugger in the eighteenth century [76] but was not widely adopted until rediscovered by Corvisart in the early nineteenth century. Done correctly, with the plexor finger tapping sharply and briefly at right angles to the middle phalanx of the pleximeter finger, it gives both audible and palpable information on the resonance of tissues beneath. Its value in assessing effusion, pleural thickening, collapse and consolidation by dullness is well known, as is its use in detecting (by increased resonance) pneumothorax and both generalized and local emphysema. As with all chest signs, comparison needs to be made with the other side and also with other parts of the same lung. Percussion is also of value in detecting overinflation, with loss of cardiac dullness and depression of liver dullness, and mediastinal shift. Less well known is its use in detecting reduced or paradoxical movements of the diaphragm, when percussion posteriorly at the end and beginning of a deep inspiration can give a reasonably accurate indication of extent and direction of movement.

### Auscultation

#### Breath sounds

The physical signs on auscultation of the chest were described by Laënnec in 1819 in the book in which he introduced the stethoscope to the world [77]; apart from some work on the physics involved in generating these sounds, little has been added to his description since [78,79]. The normal sound of breathing is largely generated as noise of all audible frequencies by turbulent flow in the large airways [47,80] (white noise), and is conducted from there to all parts of the chest. The normal larynx probably makes no significant contribution to this sound in quiet breathing [81]. The loudness and quality of the breath sounds as heard through the stethoscope at the chest wall depend on the distance from the point of origin

and the conducting properties of the intervening tissues. Thus, over the trachea and close to the trachea over the anterior upper lobes in thin people the sounds are loud and of all frequencies. Further from the trachea the sounds become less loud and the higher frequencies are filtered out by the lung. Therefore in auscultation of the lungs in the traditional manner, comparing sides and going from apex to base, there is a clear attenuation of the intensity of breath sounds from top to bottom. Any alteration to this, so that breath sounds are relatively louder at the bases, is as abnormal as a difference in intensity between the two sides.

The intensity of breath sounds may be reduced by obesity, in which case the changes are generalized. Local attenuation may be caused by reflection of sound at the interface between lung and pleural effusion/thickening or pneumothorax. In addition, emphysema is a well-known cause of reduction in breath sound intensity [82]. This is most marked when bullae are present, although gross emphysema of any type can cause it. Indeed, several studies have indicated a relationship between breath sound intensity and regional ventilation as measured by radioactive xenon [83,84], and it has been suggested that some of the inspiratory component of the breath sounds may even be generated in peripheral lung airways [85]. Collapse or partial collapse of a lobe or lung usually causes diminished breath sounds, though there may also be better conduction of the higher frequencies. This change in the frequency spectrum of the breath sounds, with more of the higher frequencies transmitted from the central airways, is called bronchial breathing. Such sounds are often no louder than normal breath sounds. They are characteristic of pneumonic consolidation but may also be heard over a collapsed lung, particularly if the obstruction causing the collapse (such as retained sputum) has been removed. Bronchial breathing may be associated with the sign of whispering pectoriloquy, in which the sounds of the whispering voice are clearly audible through the stethoscope over the area of consolidation.

The general availability of chest radiographs removes one of the major disadvantages of clinical examination of the chest, the inability to detect even large peripheral tumours that are neither obstructing major bronchi nor close to the chest wall. An ingenious physical sign that overcomes this disadvantage has been described, in which auscultation is used to assess the transmission of the sound of percussion on the other side of the chest [86]. This technique clearly requires much practice, but may be of value to the doctor without ready access to radiography.

### Added sounds

In addition to the sounds of breathing, added noises may be heard in an abnormal chest. The nomenclature of these in the English language literature has been confused,

largely because of overinterpretation or oversimplification of Lænnec's original descriptions [87]. The French word *râle* and the Latin word *rhonchus* were used by Lænnec synonymously to include all added sounds. It is therefore preferable to avoid either of these words when referring to a particular type of added sound. Modern French usage classifies the sounds as fine and bubbling crackles and high- and low-pitched wheezes [88] (*râles crépitants, sous-crépitanants, sibilants et ronflants*) together with pleural friction. This is very similar to Lænnec's original usage and to the classification suggested by Robertson [87] (Table 6.6).

The continuous musical note of a wheeze is generated by vibration of an airway at the point of closure. Acceleration of airflow through a narrowing airway, from the Bernoulli effect, causes a reduction in pressure in that airway and therefore tends to close it. This in turn reduces the flow and the airway opens again. This rapid vibration generates the wheeze, the pitch of which depends on the speed of vibration and not on the size of the airway [89]. Thus classification of a wheeze by its pitch is not particularly helpful. Wheezes of many different notes (polyphonic wheezes) are heard characteristically in asthma and chronic airflow obstruction. Each note represents an airway at the point of closure. These wheezes occur during both inspiration and expiration. Disappearance of the wheeze in a patient with an acute attack of asthma may indicate clinical deterioration, when the flow rates are no longer sufficient to generate vibration in the walls of the airways. Similarly, patients with severe airflow obstruction due to emphysema may have no wheeze at all because of low rates of airflow. Thus the presence or absence of wheeze alone is not a reliable indicator of the presence or severity of airflow obstruction. Wheeze comprising a single note (monophonic wheeze) necessarily comes from a single airway; while this is frequently heard in asthma and bronchitis, probably due to one airway being partially blocked by mucus or thickened walls, it may also be a sign of partial obstruction by neoplasm. If mucus is the cause, the wheeze can be removed by coughing. If a tumour or other organic narrowing is present, the wheeze may be modified by asking the patient to lie on his or her side. When the narrowed bronchus is in the uppermost lung it is expanded by the greater distending forces acting upon it and the wheeze may disappear. In the lower lung, the airway is narrowed further, resulting in either accentuation of the wheeze or, if bronchial narrowing is critical, loss of both wheeze and breath sounds. A similar technique can be applied to investigating possible obstructive emphysema, listening to the relative intensity of breath sounds with the patient lying first in one and then in the other lateral position.

The interrupted sound of a crackle may be generated by air bubbling through mucus in large airways. This sound has a coarse explosive quality and is modified by taking

**Table 6.6** Some classifications of lung sounds. (Adapted from Murphy [79]).

Acoustic characteristics	American Thoracic Society nomenclature	Some textbook terms	Our usage	Läennec's terms	Läennec's model
Discontinuous, interrupted explosive sounds, low pitch, loud	Coarse crackle	Coarse râle	Coarse crackle	Râle muqueux ou gargouillement	Escape of water from a bottle with mouth held directly downwards
Discontinuous, interrupted explosive sounds, less loud and shorter duration, higher pitch, repetitive	Fine crackle	Fine râle or crepitation	Fine crackle or crepitation	Râle humide ou crêpitant	Crackle of salt in a heated dish
Continuous sounds, longer than 250 ms, high pitch, dominant frequency of 400 Hz or more	Wheeze	Sibilant rhonchus	High-pitched wheeze	Râle sibilant sec ou sifflement	Prolonged whisper, chirping of birds
Continuous sounds, longer than 250 ms, low pitch, dominant frequency about 200 Hz or less	Rhonchus	Sonorous rhonchus	Low-pitched wheeze	Râle sec sonore ou ronflement	Snoring, cooing of a wood pigeon

deep breaths or by coughing. Indeed, very coarse crackles may be cleared by a good cough, which often reveals the cause as a piece of sputum. Finer crackles, often called crepitations, are of two sorts. The most widely recognized are explosive high-pitched sounds that occur in the later parts of the inspiratory cycle [89]. Several occur in each cycle and are repeated in subsequent cycles, even after coughing or deep breathing. They resemble the sound of hair rolled between the fingers close to the ear. Each crackle occurs at a particular transpulmonary pressure and represents the opening of a small airway that was previously closed [90]. Such crackles are heard in pulmonary fibrosis and oedema, allergic alveolitis, bronchiectasis and cystic fibrosis, and pneumonic consolidation, particularly as resolution begins. They are also commonly heard over a resolving collapsed lobe or segment and over infarcted lung. Auscultation at the lung bases of elderly patients first thing in the morning often reveals repetitive late inspiratory crackles; however, these disappear after a few deep breaths. In general, these crackles are gravity dependent, i.e. they occur in the dependent part of the lung. However, in allergic alveolitis (which characteristically affects bronchioles as well as alveoli) they may be quite widespread, while in pneumonia they are heard over the consolidated area of lung.

Lower-pitched explosive crackles may be heard in expiration and early in inspiration [91]. These are common in severe airflow obstruction, being associated with a forced expiratory volume in 1 s (FEV<sub>1</sub>)/forced vital capacity ratio

of less than 45%, and are often audible through a stethoscope held at the patient's mouth. They may be followed by an end-inspiratory wheeze. They are thought to represent intermittent obstruction in a larger airway, either related to abnormal collapse of the wall or to partial obstruction by secretions. They are not affected by posture and tend to be less profuse than the late inspiratory crackles discussed above. In patients with bronchiectasis, a variety of crackles may be heard, including all three types mentioned [92]. However, they typically occur in the early and mid phase of inspiration and tend to fade by the end of inspiration. They are not necessarily associated with severe airflow obstruction but may be heard at the mouth. Like the crackles associated with severe airflow obstruction, they are probably related to a combination of secretions in, and increased compliance of, larger airways.

### Pleural rub

The noise generated by inflamed pleural membranes may be quite characteristic and has been compared to the creaking leather of a new pair of shoes. Perhaps this simile is less useful to a younger generation in this era of synthetic materials. It may usually be heard on both inspiration and expiration, although the expiratory component may not be present. It is also sometimes possible to detect a superficial quality to the sound. However, when it is soft and confined to inspiration, it may be impossible to distinguish from repetitive inspiratory crackles.

## Conclusions

The clinical examination of a patient's respiratory system, as of any other, is intended to provide the physician with a picture of how that person's life and function varies from what the physician regards as normal. In the case of the pulmonary system much more information may be gained by these simple techniques than in examination of most other body systems. Thus it is possible to obtain information about the anatomy of the lungs, in terms of size and shape, displacement of mediastinal structures, state of inflation and position of the diaphragm. Sufficient physiological information can be obtained from the history and from observation of breathing and colour and chest and diaphragmatic movements to allow the experienced physician to make a reasonable estimate of vital capacity

and residual volume. With the addition of the simple test of timing a forced expiration, an estimate of FEV<sub>1</sub> can be added [93,94].

Finally, much information of a pathological nature may be inferred from the finding of abnormalities of structure and function and from knowledge of the most likely causes of these abnormalities. Indeed, it should be an infrequent event for the chest physician not to have a very good idea of the cause of a patient's symptoms at the end of a clinical consultation, supplemented by radiographic examination of the chest. This, together with the ready availability of simple tests of lung function such as peak expiratory flow rate and FEV<sub>1</sub>, should allow quick decisions to be made and appropriate management to be planned without delay, a most important factor in the handling of worried patients.

# DIAGNOSTIC IMAGING

ARTHUR J.A. WIGHTMAN

## Chest radiography

The chest radiograph is the most frequently performed radiological investigation. Broad guidelines for its use have been drawn up by the Royal College of Radiologists [1] that recognize the requirement to avoid unnecessary patient irradiation when the diagnostic yield would be negligible. Until considerable experience in reading chest films has been gained, it is useful to have a methodical system for analysing each one.

### Indications

Chest radiographs are indicated when new lower respiratory, cardiac or other intrathoracic disease is suspected. Common examples include pneumonia, tuberculosis, malignancy, pleural effusion, myocardial infarction, or other undiagnosed causes of chest pain, dyspnoea or haemoptysis. Chest radiographs are generally not justified in the following circumstances:

- 1 pre-employment or screening medicals, except in a few high-risk groups (e.g. at-risk immigrants with no recent film) or for certain specific occupations (e.g. professional divers);
- 2 preoperatively in the absence of any suspected respiratory or cardiac disease;
- 3 in the routine follow-up of patients with chronic bronchitis and emphysema, asthma, heart disease or hypertension, unless the symptoms and signs have changed.

There are certain other instances when patients are sometimes referred inappropriately. For example, it is never necessary to obtain both right and left lateral views, it is seldom necessary to obtain an expiration as well as inspiration film in suspected pneumothorax, and follow-up films in pneumonia should not be obtained more frequently than every 7–10 days unless the clinical condition is deteriorating or a complication such as empyema is suspected. Pneumonia has a mean resolution time of 6 weeks, and is often much slower to clear in the elderly.

## Anterior views

The standard radiograph is the posteroanterior (PA) view; this may be supplemented with a lateral view. A reasonably accurate record of true cardiac size is obtained from the PA film, and fluid levels in lung cavities can be detected since the patient is examined in the erect position. Voltages in the range of either 60–75 kV<sub>p</sub> or in excess of 135 kV<sub>p</sub> are customarily used. With the former, the greater part of the lungs and bony detail of the ribs are seen well and ectopic calcification is readily recognized. The major disadvantage is that the mediastinum and those parts of the lungs behind the heart and behind the domes of the diaphragm are imperfectly shown. These blind areas of the lungs, as well as the trachea and main bronchi, the thoracic spine and certain of the mediastinal pleural reflections, are shown to advantage with a high kilovoltage technique and recognition of small lung nodules (as in pneumoconiosis) is improved. However, calcification in thoracic lesions is less readily appreciated and detail of bone structures is impaired because the absorption coefficients of soft tissue and calcium approximate to each other with increased kilovoltage.

An anteroposterior (AP) view is taken when the patient is insufficiently fit for a PA chest film. It may also be useful in providing a supplementary view, offering a slightly different projection to the PA view. For example, it may resolve whether a shadow seen on the PA view represents a true pulmonary lesion or an overlap of normal structures, or alternatively whether a small opacity lies in rib or lung. Variable magnification of the cardiac image occurs so true assessment of cardiac size cannot be obtained from the AP view.

The scheme outlined in the sections below is suggested for comprehensive analysis of the anterior chest film (Fig. 7.1). After completing the analysis, it may be extremely useful to compare current findings with those shown on previous films. For instance, confirmation that an abnormality is long-standing may eliminate the need for further investigation, and previous films are essential for

**Fig. 7.1** PA chest film of female showing central position of trachea (black arrow); mid-point of V-shaped right hilum (large white arrow); and shadow of aortic arch and lateral border of descending thoracic aorta (small white arrows).

monitoring the progression of disease or its response to treatment.

### *Preliminary observations*

#### *Is the patient straight?*

Compare the positions of the medial ends of the clavicles (anterior structures) relative to the sides of the thoracic vertebral bodies at the same level (posterior structures). The relationships should be symmetrical on the two sides. It is important to check this since rotation of the patient to one side brings more soft tissue of the chest wall and breast across the opposite lung, which may give a false impression of loss of normal lung transradiancy on that side.

#### *Is the film adequately penetrated?*

On a film of adequate penetration it should be possible to see the disc spaces between the thoracic vertebral bodies. If this is not so, the film is underpenetrated and important information in the lung behind the heart and domes of the diaphragm may be lost.

#### *Is the examination PA or AP?*

It is usually impossible to tell from the configuration of the chest whether the patient has been examined in the PA or

AP view. This information may be provided by the inscription on the film: labelling with 'portable' or 'P' or 'supine' indicates an AP examination. Knowledge of the projection is needed to determine if a true or magnified image of the heart has been obtained.

#### *Are accompanying chest films of the same patient?*

Occasionally one of a patient's chest films appears strikingly different from others, and the question arises of possible mislabelling or mixing of radiographs of patients with the same name. The most individualistic feature on a chest film is the pattern of calcification of the costochondral junction and costal cartilages of the first ribs, and comparison of these will quickly determine if the films are of the same or different patients.

### *Diaphragm*

On inspiration the hemidiaphragms normally lie between the anterior ends of the fifth and seventh ribs. A check of diaphragm position is important since apparently increased lung density or basal atelectasis may be due purely to poor inspiration in an unconscious or uncooperative patient. Usually the right hemidiaphragm is up to 1.5cm higher than the left. The situation is reversed with dextrocardia. When the left hemidiaphragm is higher than the right, a cause such as collapse of the left lower lobe or a subphrenic abscess should be considered. However, the left hemidiaphragm may on occasion be higher than the right as a normal finding.

### *Heart*

A check should be made of cardiac position. Normally between two-thirds and three-quarters of the diameter of the heart lies to the left of the midline, with one-quarter to one-third to the right. Displacement may be due to lobar collapse, tension pneumothorax, etc. Heart size should also be noted. It is rare in health to find a maximum cardiac transverse diameter exceeding 15.5cm; this is therefore a useful working upper normal diameter, although 1–2% of healthy people, usually of large physique, have a cardiac diameter in excess of this figure. Alternatively the cardiothoracic ratio (maximum cardiac transverse diameter/maximum transverse diameter of the thorax, measured to the inner aspect of the rib cage on each side) may be assessed and is usually less than 50%, although it may sometimes be greater than this in healthy people, for example trained athletes.

### *Trachea*

Assessment of the position of the trachea can next be made. It is normally central at the thoracic inlet but lies a

little to the right of the midline within the chest where it is crossed by the aortic arch.

### *Hila*

The normal hilar shadow is in the shape of a letter V lying on its side, the lower limb of the V being formed by the lower lobe branch of the pulmonary artery and the upper limb by the upper lobe veins crossing the hilum to reach the left atrium. The walls of the bronchi are too thin to contribute to the hilar shadows, and hilar lymph nodes are only visible when pathologically enlarged. The apex of each V-shaped hilum can usually be clearly identified. The apex of the right hilum normally lies at the level of the sixth rib in the mid-axillary line, while the apex of the left hilum is some 1–1.5 cm higher. It is important to take note of the hilar positions since displacement may provide a clue to lobar collapse. The hila may also be displaced by localized lung fibrosis, secondary for example to old tuberculosis or radiotherapy. Hilar enlargement may be due to enlargement of the pulmonary vessels (e.g. in cor pulmonale), lymph node enlargement or the presence of a primary hilar neoplasm. This is discussed later in the chapter.

### *Horizontal fissure*

In some 80% of chest radiographs part of the horizontal fissure separating the upper from the middle lobe can be identified. This normally runs almost horizontally, although an angulation of 10° upwards or downwards may not be significant, and lies in the line between the apex of the right hilum and the sixth rib in the mid-axillary line. Displacement occurs in lobar collapse, lobar shrinkage from previous destructive lung disease, or with large bullae.

### *Lungs*

It is convenient next to compare the two lungs zone by zone for any increased or decreased shadowing that may be present. The lungs may be divided for descriptive purposes into zones: the upper zone represents the region from the lung apex to the lower border of the second rib anteriorly; the mid zone is from the lower border of the second rib to the lower border of the fourth rib anteriorly; and the lower zone is the region below this. This division allows description of the site of the lesion on an anterior view but avoids the need for anatomical localization to a specific lobe, for which a supplementary lateral view or more complex imaging may be required. Note should be made of the characteristics and density as well as location of any lung abnormality, and particular care should be taken to inspect the regions behind the heart, behind the domes of the diaphragm and in the planes of the hila and

clavicles, these representing less readily seen areas in which abnormalities may be overlooked.

### *Soft tissues*

Unless attention is paid to the soft tissues of the chest wall, a previous mastectomy as a cause for unilateral hypertransradiancy may be overlooked. Nodules on the chest wall are silhouetted by air and may simulate lung nodules. Thus the cutaneous nodules of neurofibromatosis may be mistaken for pulmonary nodules when they are seen superimposed on the lungs, but their true nature will be recognized when similar nodules are identified on the skin surface outwith the planes of the lungs. Other causes of soft-tissue loss or increase, with or without displacement of the subcutaneous fat lines, and the recognition of air or calcification in the soft tissues may provide clues to the origin and nature of a chest radiographic abnormality.

### *Skeleton*

A search should be made for bony abnormalities contiguous with, or remote from, lesions of the lung. Thus ribs may be destroyed by carcinoma from direct extension of tumour to the chest wall or from haematogenous metastases; rib fractures may explain the presence of a pleural effusion; and pressure erosion (as distinct from destruction) may be seen on the undersurface of ribs at the site of an intercostal neuroma or in aortic coarctation. Very florid 'pseudocallus' occurs round healing fractures in patients with Cushing's syndrome and those on steroid therapy, and may be mistaken for lung nodules unless their relationship to bone is appreciated. Recurrent chest infection can be a presenting symptom of multiple myeloma, the diagnosis of which is suggested by multiple small clearly defined lytic lesions in the ribs, shoulder girdles or proximal humerus. Lytic metastases, for example from breast, can simulate myeloma deposits, although metastases are usually less clearly circumscribed. Bone density may be increased, the causes of several or numerous areas of sclerotic or mixed sclerotic and lytic lesions being most commonly breast carcinoma in female and prostatic carcinoma in male patients (Fig. 7.2). Carcinomas of other origin, including bronchial carcinoma, lymphoma, myelofibrosis, mastocytosis, and fluorosis in patients from endemic areas, are rarer causes of widespread sclerosis. Increased bone density is also seen in conjunction with modelling deformities, locally in Paget's disease and fibrous dysplasia and generalized in osteopetrosis. The shoulders should be inspected routinely, since these may show skeletal changes of a disease process affecting the chest (e.g. rheumatoid arthritis) or the effects of treatment of chest disease (e.g. avascular necrosis of the humeral head from steroid therapy).

**Fig. 7.2** Sclerotic and lytic (arrows) metastases in ribs and scapula in patient with prostatic carcinoma.

### Lateral view

The lateral view localizes an abnormality shown on an anterior view, may provide improved detail and characterization of such an abnormality, and occasionally may reveal a lung lesion that is invisible on the anterior view. For this last reason, it is important to obtain a lateral view in a patient with suspected bronchial carcinoma or other serious condition in whom the anterior view is negative. The lateral film can be analysed in a similar way to that described for the anterior view. Although lung detail is lost to some extent due to superimposition of the two sides, the retrosternal and retrocardiac areas of lung are seen with reasonable clarity (Fig. 7.3). The thoracic vertebrae should appear increasingly transradiant from top to bottom; sometimes the only evidence of lower lobe collapse or of other disease of the lower lobe is that the lower thoracic vertebrae appear as opaque as, or more opaque than, the upper. A lateral view is also sometimes helpful in showing unequivocal interstitial disease of the lung bases

**Fig. 7.3** Left lateral film showing trachea (1), aortic arch (2), pulmonary artery (3), left lower lobe bronchus (4) and oblique fissure (5), and edges of scapulae (6).

when this is uncertain on the anterior view because of superimposition of dense breast shadows.

### Computed tomography

Computed tomography (CT) has an established place in the investigation of pulmonary, mediastinal, hilar and pleural disease. Multiple cross-sectional images provide far more information than is available from the chest radiograph. For example, subpleural metastases may only be visible on CT, and mediastinal masses such as enlarged lymph nodes can be readily identified and located, particularly if a contrast-enhanced scan, entailing the intravenous injection of an iodine-containing contrast medium, is performed to distinguish vascular from low-vascularity or cystic structures.

Images of slices 5–10 mm thick are acquired while the X-ray tube and detectors rotate round the transverse axis of the patient. On early scanners rotation was limited on each exposure to 360° by the physical restraints of connecting cables and the patient was scanned in a repetitive scan–table movement–scan–table movement sequence, the tube and detectors rewinding back to their original positions before each scan. This slow stop–start procedure

required the patient to rebreathe and suspend respiration before every one or two scans; consequently lung lesions of up to 1.5cm diameter could be missed if the patient failed to do this at the same depth of inspiration before each scan, leading to gaps between neighbouring images [2].

Spiral (helical or volumetric) scanners have now superseded the earlier scanners. These use electro-optical slip rings instead of cables, such slip rings allowing for indefinite unidirectional rotation of the X-ray tube and detectors. During exposure the X-ray table slides longitudinally in a continuous movement and the entire chest can be scanned in a spiral action during one or two breath-holds. The problem of volumetric gaps due to different degrees of suspended respiration is therefore eliminated. Further advantages are that image reconstructions can be made embracing any thickness of a single or two contiguous cuts, and these can give much more positive detail of lesions such as small lung nodules. Coronal, sagittal and three-dimensional reconstructions can be made from such volumetric axial scans.

High-resolution CT (HRCT) of the chest is used when there is a need to examine subtle lung changes in maximum detail. The technique entails scanning the chest with thin-section cuts of 1–2mm thickness and employing data reconstruction using a high spatial frequency algorithm to maximize spatial resolution. Scanning very thin sections avoids including detail of overlapping structures on the cross-sectional image, and thus the clarity of the image is akin to looking at a cross-section of inflated lung with the naked eye. The effect of a high spatial frequency algorithm is to produce much sharper tissue interfaces with improved resolution. In contrast to volumetric scanning as described above, in which full coverage of the lungs may be sought, HRCT involves sampling tiny volumes of the lung, usually at intervals of 1–2cm, or more closely through a predetermined region of interest. The chief applications of HRCT can be summarized as follows.

- 1 Most instances of diffuse lung disease; however, for obvious reasons, a search for lung metastases requires a comprehensive examination of the lungs with thick cuts.
- 2 In bronchiectasis HRCT has replaced bronchography although correlation is not perfect.
- 3 Sometimes in focal lung disease, e.g. for detection of contained fat or calcium.

Radiation dose to the patient from chest CT is relatively large and highly variable. While the dose in planned limited HRCT may be similar to that from two pairs of PA and lateral chest radiographs, in full-volume scanning it is much higher and can be in excess of the dose from 150 chest films, two intravenous urograms or one barium enema [3]. For this reason the requirement for CT, and particularly for repeat scanning, should be carefully weighed in each case.

## Ultrasound

Ultrasound is an important aid in the investigation of pleural disease and in the search for subphrenic conditions (e.g. subphrenic abscess) that may be causing abnormalities of the lung or pleura. The wave frequencies used in diagnostic practice do not penetrate air and therefore ultrasound is not useful in the investigation of intrathoracic lesions where these are separated from the chest wall by aerated lung. Ultrasound is used to demonstrate an effusion concomitant with extensive consolidation when this cannot be confirmed from radiographs. Demonstration of such fluid is important before thoracocentesis is attempted. Pleural tumour, concealed on radiographs by a large accompanying pleural effusion, may also be shown by ultrasound.

Sonography can facilitate drainage of small effusions by providing precise localization of the pleural fluid. It may similarly be used as an alternative to fluoroscopy to assist percutaneous needle biopsy of pleural or pleural-based tumour. This is particularly useful when the pleural opacity is shallow and not easily seen in more than one plane on the radiograph. It is often simpler to confirm and localize small pleural effusions by ultrasound than by radiography in critically ill, immobile patients. If required, pleural aspiration can then be carried out with sonographic assistance at the bedside.

## Lung scintigraphy

Ventilation–perfusion ( $V/Q$ ) or perfusion ( $Q$ ) scanning alone is the primary investigation for pulmonary thromboembolism. The principle is that pulmonary emboli produce areas of defective perfusion of lung without corresponding abnormality in ventilation. Since the aim is to determine if perfusion is abnormal, it follows that a ventilation scan is superfluous in the investigation of pulmonary thromboembolism when the perfusion scan is normal. However, there is a technical advantage in performing the ventilation scan first, since the images from xenon ventilation scans are degraded in quality by scattered photons produced by technetium from a recent prior perfusion scan, and moderate-sized foci of airways obstruction may be overlooked. In practice, therefore, both ventilation and perfusion scans are usually performed, although perfusion scanning alone is sometimes carried out when there is little possibility of airways obstruction.

During ventilation scanning, sequential posterior images of the lungs are obtained while the patient breathes air containing approximately 75–80 mega Bq of  $^{133}\text{Xe}$ . At the end of the wash-in phase, equilibrium images are obtained on rebreathing through a closed system, followed by wash-out images until the xenon has cleared from the lungs or 10 min have elapsed. For perfusion

imaging, 75–80 mega Bq of  $^{99m}\text{Tc}$ -macroaggregated albumin are injected intravenously, this effectively producing iatrogenic pulmonary microemboli, and images including posterior, anterior, and anterior and posterior oblique views of both lungs are obtained.

### Diagnosis of pulmonary thromboembolism

The chest radiograph is of very limited value in the diagnosis of pulmonary thromboembolism. The majority of emboli produce no radiographic change; when abnormality is present it is usually non-specific, consisting of an area of consolidation, linear band shadows from atelectasis, pleural effusion or hemidiaphragmatic elevation. Therefore the main differential diagnosis is pneumonia. Occasionally more specific chest radiographic changes are seen, such as development of hilar vessel enlargement (from mechanical plugging of the pulmonary arteries by clot) or unilateral or lobar hypertransradiancy. These infrequent changes are more readily recognized when recent previous films are available for comparison. A further limitation of the chest radiograph is that non-specific changes such as consolidation take a minimum of 12–24 h to develop, so that signs are not found immediately after the clinical event.

V/Q scanning is the investigation of choice in suspected pulmonary embolism; in contrast to the chest radiograph, the Q scan is abnormal immediately after the event. While V/Q scanning is highly sensitive, it is relatively non-specific and pulmonary embolism is overdiagnosed unless careful criteria for interpretation are used. Based on studies comparing V/Q scanning with pulmonary angiography [4–6], the following protocol is used in the author's institution, classifying scans as normal, of high probability for pulmonary embolism, and non-diagnostic. For interpretation of the scan a recent chest film is required, since perfusion abnormalities that correspond exactly with radiographic changes are not diagnostic.

**1 Normal:** no perfusion abnormality and a normal chest radiograph, or perfusion abnormality that exactly outlines a non-pulmonary chest radiographic finding (e.g. hilum, unfolded aorta).

**2 High probability:**

- (a) two or more large segmental perfusion defects (each  $\geq 75\%$  of the volume of a segment) either without corresponding ventilation or chest radiographic abnormality, or substantially larger than either matching ventilation or chest film abnormality; or
- (b) two or more moderate segmental perfusion defects ( $\geq 25\%$  and  $\leq 75\%$  of a segment) without matching ventilation or chest radiographic abnormality, plus one large unmatched segmental defect; or
- (c) four or more moderate segmental perfusion defects without ventilation or chest radiographic abnormality.

**3 Non-diagnostic:** any scan that is not high probability or

normal, or a scan that has no perfusion defect but where the chest film shows a radiographic abnormality consistent with a pulmonary infarct (e.g. atelectasis, pleural-based infiltrate).

A normal scan effectively excludes pulmonary embolism demonstrable by any other means and no further investigation is required. A high-probability scan using the above criteria has a specificity exceeding 90% and treatment can be instituted. Further investigation is required in those patients with non-diagnostic scans. While pulmonary angiography would seem the logical next step, the large number of patients falling into this category, and the invasiveness, morbidity and specialist time required for angiography, render this an unrealistic option in many centres. For these reasons lower limb venography or Doppler offer an alternative next step by determining if there is evidence of a source in the legs for emboli to the lungs. The combination of positive venography or Doppler and an indeterminate scan provide a good argument for instituting treatment with anticoagulants, while the combination of negative venography or Doppler and an indeterminate scan require further consideration. In these circumstances investigation may be stopped when there is a low clinical suspicion and there are no risk factors for pulmonary embolism, while angiography is required when the clinical suspicion is high or risk factors are present.

Angiography is the final arbiter in the investigation of pulmonary embolism, positive signs being the outlining of intraluminal thrombus (Fig. 7.4) or abrupt obstruction of flow by thrombus. However, spiral CT angiography, where available, is becoming established as a less invasive alternative.

### Spiral CT pulmonary angiography

The shortcoming of V/Q scanning for pulmonary embolism is that the majority of scans ( $>60\%$ ) are equivocal (of intermediate or low probability) [7]. Where spiral CT is available, CT pulmonary angiography provides an alternative means of investigation. The lungs are scanned from the top of the aortic arch to the inferior pulmonary veins in thin, usually 3-mm, contiguous sections during intravenous infusion of contrast. The data can be manipulated to construct thinner sections for analysis if required.

Thrombus is seen as a filling defect within a main or segmental pulmonary artery (Fig. 7.5). Commonly a thin layer of blood lies between the thrombus and the vessel wall, creating a 'railway track' or 'polo mint' appearance (Fig. 7.6). Thrombus in vessels below segmental level is not reliably detected by CT pulmonary angiography. CT may also show supportive signs of pulmonary embolism, such as a small effusion or pleural-based segmental or subsegmental consolidation. Alternatively it may reveal

Fig. 7.4 Pulmonary arteriogram showing normal right upper lobe vessels but thrombus (arrows) present in lower lobe artery.

an unsuspected cause for the patient's symptoms, such as aortic dissection or unrelated chest disease.

Reports of the use of CT pulmonary angiography for the investigation of pulmonary thromboembolic disease are favourable, with sensitivities and specificities of 90% or better [8]. Large multicentre studies are currently in progress. The disadvantages of CT angiography compared with  $\dot{V}/\dot{Q}$  scanning are the increased burden on available CT time, increased radiation dose and the small risk of severe adverse reactions to contrast medium. CT angiography may be seen as a useful first investigation of patients in whom massive pulmonary embolism is suspected, or in situations in which a  $\dot{V}/\dot{Q}$  scan is likely to be indeterminate (e.g. history of pre-existing cardiorespiratory disease, abnormal chest radiograph).  $\dot{V}/\dot{Q}$  scanning remains a useful first investigation for pulmonary embolism in young to middle-aged patients without pre-existing cardiopulmonary disease where massive embolism is not suspected. Spiral CT is replacing conventional pulmonary angiography since it is non-invasive and less dependent on the skills of the operator.

### Magnetic resonance imaging

Both CT and magnetic resonance imaging (MRI) define lung nodules, lymph nodes and other masses in the hila and mediastinum, and vascular structures of the thorax. CT is preferred to MRI for the investigation of most chest disorders: data acquisition is quicker, cardiac gating is not required, spatial resolution is greater and recognition of calcification is much better. However, there are instances in which the superiority of MRI is recognized. Thus MRI is the better investigation for lesions of the spine and paraspinal region. Lateral thoracic meningoceles and

Fig. 7.5 Spiral CT arteriogram: the left pulmonary artery is filled with thrombus (arrows) and the right is clear.

**Fig. 7.6** Spiral CT arteriogram: 'polo mint' sign produced by a thin rim of contrast between thrombus and arterial wall (arrows).

**Fig. 7.7** MRI showing left superior sulcus tumour. The subclavian artery, spinal nerves and brachial plexus are clearly seen on the normal right side, contrasted by high fat signal. The carcinoma at the left apex in contrast is seen infiltrating the fat planes and invading the brachial plexus.

paraspinal neurofibromas are demonstrated well, and their exact relation to the intervertebral foramen and vertebral canal can be characterized further if necessary with coronal, parasagittal and other reconstructions. Furthermore, MRI may be superior to CT in showing early tumour invasion into the chest wall or mediastinal structures and is particularly helpful, for example, in mapping tumours extending into the brachial plexus [9] (Fig. 7.7). It therefore has a place in the preoperative investigation of lung cancer where the possibility of such invasion is raised by CT or other investigations.

In the cardiovascular system, MRI is valuable in elucidating complex congenital abnormalities of the heart and shows aneurysms and other abnormalities of the great vessels. While MRI angiography has shown potential in the diagnosis of pulmonary embolism, this application is largely being superseded by the advent of spiral CT angiography.

MRI has the advantage over CT of not involving ionizing radiation. It may therefore be used safely in patients requiring follow-up scans to gauge response to treatment, for example the response of lymphoma to chemotherapy,

or in the reappraisal of aortic dissections and in the investigation of children.

## Other methods of investigation

### Fluoroscopy

By viewing the chest during fluoroscopy during different phases of respiration or patient rotation, it can be readily determined if a chest radiographic opacity is located in lung, rib or chest wall and, if intrathoracic, its site and relationship to normal anatomical structures can be assessed. Fluoroscopy and ultrasound are equally accurate in confirming paralysis of a raised hemidiaphragm.

### Tomography

Linear tomography has been largely replaced by CT, which determines with much greater accuracy the existence and site of hilar lymphadenopathy, the characteristics of a thoracic lesion (e.g. whether it contains calcification or fat) and the presence of pulmonary metastases and interstitial lung disease. Conventional tomography suffers from the limitation that the borders of normal and abnormal mediastinal tissues are only defined where they are silhouetted by air in adjacent lung or trachea. In contrast, on CT the borders of mediastinal structures are outlined by surrounding fat, while artificial contrast between vascular and low-vascularity structures can be created with intravenous contrast medium.

### Barium swallow

Barium swallow examination may be useful in detecting upper gastrointestinal abnormality that accounts for chronic cough or recurrent aspiration pneumonia (e.g. pharyngeal pouch, achalasia).

### Pulmonary and bronchial angiography

Pulmonary angiography is the most sensitive examination for the detection of pulmonary thromboembolism. CT has largely replaced angiography in the assessment of aortic dissection; longitudinal reconstructions showing the extent of an aortic dissection can be made from the CT axial imaging data if required (Fig. 7.8). Transoesophageal echocardiography may also be employed, while MRI is probably the most accurate examination for dissection but suffers from the constraint that it may affect some life-support systems. Angiography is largely reserved for situations where the above examinations are equivocal.

Bronchial arteriography and embolization provide an alternative to surgery in situations of severe haemoptysis due to benign conditions such as bronchiectasis and bleeding from old tuberculous cavities. Such intervention can be life-saving, although there is a tendency for haemoptysis to recur as other feeding vessels bleed in turn. Arterial embolization has also increasingly replaced surgery in the management of shunts and haemoptysis from pulmonary arteriovenous fistulae.

## Consolidation and collapse

### Lobar consolidation

The term 'consolidation' embraces those conditions that cause replacement of air-containing lung by fluid-filled or

Fig. 7.8 Longitudinal reconstruction of CT scan showing aortic dissection (arrow).

cellular tissue without change of volume. The causes are therefore numerous and are discussed in other chapters. This section describes the radiological features.

In lobar consolidation the affected lobe is opaque, the region of opacity corresponding with the normal anatomical position of the lobe and clear linear demarcation from normal lung being produced by curtailment of the consolidation at the respective fissure or fissures. The patterns of consolidation of the different lobes are illustrated in Figs 7.9–7.16. Accumulation of fluid in a lobe is to some extent influenced by gravity, so there is a tendency for the consolidation to be maximal in the dependent part of the lobe, or posteriorly if the patient has been lying supine. The most specific sign of consolidation is the air bronchogram, seen as black branching tubes and representing air-filled bronchi silhouetted by surrounding fluid-filled lung (Fig. 7.17).

The diaphragm and lateral borders of the mediastinum are visible on a normal chest radiograph because they are silhouetted by adjacent low-density lung. Consolidated lung has the same radiographic density as soft tissue, so the normal silhouette of the heart border or diaphragm is lost when consolidation develops in adjacent lung. Application of this principle, the silhouette sign, is useful in determining from an anterior radiograph the lobe involved in consolidation. For example, the heart border is obscured in middle-lobe or lingular consolidation (Figs 7.11 & 7.13) but is preserved in lower-lobe consolidation when the diaphragm may be obscured.

Consolidation is often patchy and non-lobar in distribu-

tion and can be due to a great variety of causes, e.g. pneumonia, oedema, haemorrhage or pulmonary infarction. Frequently the cause is not evident and it is important to consider the radiographic findings in conjunction with the clinical and laboratory parameters in each case. Sometimes the location and characteristics of the consolidation suggest the cause, e.g. patchy consolidation associated with areas of cavitation in the upper thirds of the lungs is likely to be due to pulmonary tuberculosis.

The consolidation of pulmonary oedema can be patchy and non-specific. The diagnosis is suggested if it is perihilar and bilateral, particularly if associated with cardiomegaly, Kerley lines (see below) and pleural effusions. If the patient has been nursed on one side for several hours, the oedema may be largely confined to the dependent side. Left ventricular failure leading to pulmonary oedema often occurs in conjunction with pneumonia and it can be impossible to distinguish the relative contributions of each on the radiograph. Pulmonary oedema may clear very rapidly in response to treatment, with striking radiographic improvement in 12–24 h; this rapidity of clearing is one sign that differentiates oedema from pneumonia.

Air bronchograms may be seen in certain conditions that produce cellular infiltrates in the lung, notably lymphoma, alveolar cell carcinoma and sarcoidosis. These conditions should therefore be considered in a patient with radiographic consolidation but without clinical pneumonia, or in persisting radiographic change of pneumonia unresponsive to treatment.

**Fig. 7.9** PA film showing consolidated right upper lobe.

**Fig. 7.10** Lateral film of same patient as in Fig. 7.9 showing consolidation limited inferiorly by horizontal fissure (arrows).

**Fig. 7.12** Lateral view of same patient as in Fig. 7.11 showing consolidation demarcated by horizontal and oblique fissures.

**Fig. 7.14** Lateral view of same patient as in Fig. 7.13 showing consolidation demarcated posteroinferiorly by oblique fissure (arrows).

**Fig. 7.15** PA film of left lower lobe consolidation: note left heart border is visible through consolidation (arrow).

**Fig. 7.16** Lateral view of same patient as in Fig. 7.15 showing consolidation demarcated anterosuperiorly by oblique fissure.

### Lobar collapse

In lobar collapse the affected lobe is opaque but, unlike pure lobar consolidation, is accompanied by the following changes to a variable extent: displacement of the heart and

**Fig. 7.17** Air bronchograms in right lower lobe consolidation: the black branching bronchi (arrows) are clearly outlined against the opacified lung.

trachea to the affected side, elevation of the corresponding hemidiaphragm, displacement of the fissures bounding the lobe and splaying out of the vessels in the remaining part of the lung to produce hypertransradiancy. The appearances of lobar collapse are shown in Figs 7.18–7.25. Observation of the silhouette sign may provide the only clue to middle-lobe collapse on an anterior radiograph (Fig. 7.20), since this lobe is too small to produce any significant displacement of neighbouring structures.

Differentiation on the radiograph between pure lobar consolidation and collapse is important, since lobar consolidation usually indicates a simple pneumonia that is likely to clear while lobar collapse implies the presence of an underlying bronchial obstruction that usually requires further investigation by bronchoscopy. In a middle-aged or elderly adult, lobar collapse is most commonly due to an underlying bronchial carcinoma, while in a child it may be due to an inhaled foreign body.

### Pleural effusion

Pleural fluid first collects under the lung in an erect patient. The effect is to produce apparent slight diaphragmatic elevation but, since the level of fluid is shallow and the normal position of the diaphragm is variable from individual to individual, it can rarely be detected at this stage. As the effusion increases, fluid starts to collect in the costophrenic angles, first posteriorly where the sulcus is lowest, then laterally and finally anteriorly. An effusion is therefore first visible radiographically on a lateral view, and later an anterior view, as a homogeneous opacity

**Fig. 7.18** Collapsed right upper lobe showing elevation of horizontal fissure and deviation to right of trachea.

**Fig. 7.19** Right lateral view of same patient as in Fig. 7.18 showing horizontal fissure elevated and bowed upwards and oblique fissure forwards (arrows).

**Fig. 7.20** PA view of middle-lobe collapse showing obscuration of right heart border.

**Fig. 7.21** Lateral view of same patient as in Fig. 7.20 showing retraction forwards of oblique fissure (arrows).

filling in the costophrenic angle with a concave border facing the lung. The minimum volume of fluid required for detection on a PA chest film in an erect subject ranges from 250 to 600 mL [10,11].

As the effusion increases it spreads over the lung like a mantle, forming a meniscus-shaped homogeneous opacity that is highest at the chest wall. The elastic recoil of the lung is least on its medial aspect, where it is partially

**Fig. 7.22** Left upper lobe collapse showing homogeneous density over upper and middle zones.

**Fig. 7.23** Same patient as in Fig. 7.22 showing oblique fissure pulled forwards by collapsed left upper lobe (arrows).

**Fig. 7.24** Collapsed left lower lobe showing double shadow at left heart border. The edge of the collapsed lobe is arrowed.

**Fig. 7.25** Lateral view of same patient as in Fig. 7.24 showing increase in tissue density over lower thoracic vertebrae.

tethered by the hilum and pulmonary ligament, allowing less fluid to accumulate on this surface. On an anterior radiograph the meniscus-shaped upper edge of the opacity of a moderate-sized effusion therefore slopes downwards from the lateral to the medial aspect of the hemithorax. On a lateral radiograph the anterior and posterior borders of the meniscus are at the same level, since fluid collects to an equal extent in front of and behind the lung, and this is at the same height as the top of the effusion in the axillary line seen on the anterior radiograph.

A very large effusion produces total opacification of the hemithorax. In the absence of disease of the underlying lung, this causes displacement of the mediastinum away from the affected side, and also produces marked depression and even inversion of the underlying hemidiaphragm. On the left side this is seen as downward displacement, flattening and sometimes convexity of the air-filled gastric fundus.

A very large effusion with collapse of one or more lobes of the underlying lung from endobronchial obstruction gives rise to an opaque hemithorax with little or no mediastinal or diaphragmatic displacement, the opposing effects of volume change counteracting each other. An opaque hemithorax without volume change may be seen also in extensive mesothelioma, the volume loss of the lung secondary to encasement and constriction of the hilum countering the opposing effect of an associated effusion. Total lung opacification occurs also in complete consolidation of a lung. This is rare, and an air bronchogram or evidence of patches of aerated lung within the consolidation is usually visible. A hemithorax may at first sight appear totally opaque in a patient with a moderate pleural effusion who has been examined in a supine position, but on closer inspection normal vessel markings are visible that indicate aerated lung lying in front of the pleural fluid in the posterior pleural space.

An opaque hemithorax with mediastinal displacement and elevation of the diaphragm on the affected side is produced by collapse of the lung due to central bronchial obstruction, and there may be a small accompanying effusion. A similar appearance occurs following pneumonectomy, the radiographic clue to which may be deformity of the fifth or sixth ribs posteriorly from surgical transection and partial regeneration.

While a moderate volume of pleural fluid needs to be present to be visible on chest radiography, very small quantities (as little as 10–15 mL) can be detected by ultrasound; this is the examination of choice to confirm the presence of a small effusion, to distinguish between an effusion (which changes position on change of posture) and pleural thickening (fixed), and to determine the optimum site for thoracocentesis. Where ultrasound is unavailable, the presence of an effusion can be confirmed with a lateral decubitus view or a supine view, which is

not as good but sometimes more practicable in a seriously ill patient.

### **Subpulmonary (intrapulmonary) effusion**

As mentioned above, a pleural effusion usually first collects under the lung and soon spills into the costophrenic sulci, rising over the lung like a mantle as it enlarges. On occasion, and in the absence of underlying pleural disease, the effusion continues to collect under the lung where it may accumulate to a depth of several centimetres. On the anterior radiograph this presents as an apparent high diaphragm, which therefore has to be differentiated from true diaphragmatic elevation. Several signs may enable such a distinction to be made.

1 When a subpulmonary effusion is present there is often a little fluid producing blunting in the costophrenic angle, which provides a clue to the presence of pleural fluid; on a lateral view there is similarly often a little fluid visible in the lower end of the oblique fissure.

2 The separation between the left hemidiaphragm and air-filled gastric fundus is usually no more than 1 cm, and greater separation suggests a subpulmonary collection.

3 The peak of the hemidiaphragm is normally approximately midway from side to side, while the peak of a pseudodiaphragm is often more lateral, at approximately the junction of the middle and outer thirds, with a steep slope downwards from the peak to the costophrenic angle.

If doubt persists, ultrasound or a lateral decubitus view of the chest will establish if an effusion is present, the fluid shifting to the side of the chest when the patient lies on the affected side because a subpulmonary effusion is not associated with pleural adhesions.

### **Loculated effusions and empyema**

Pleural fluid may collect in an atypical distribution when there are adhesions between the pleural layers that prevent free communication within the pleural space. An empyema, for instance, may appear as a D-shaped shadow when viewed in profile, most commonly lying posteriorly or laterally (Fig. 7.26), but when viewed *en face* presents as a much less characteristic opacity of homogeneous density. The D-shaped shadow of an empyema may simulate the appearance of a tumour of pleural or extrapleural origin, as described below. A useful point in differentiation is that an empyema is usually accompanied by a small effusion lying in a normal position at the costophrenic angle. If necessary, an empyema may be differentiated readily from a tumour mass by ultrasound. An empyema may also on occasion simulate a peripheral lung abscess, and CT with intravenous contrast injection can be helpful in differentiation [12].

Fluid may also collect within the fissures to produce an interlobar effusion. When viewed *en face* this may appear

**Fig. 7.26** Large empyema: arrows indicate upper and lower edges of the D-shaped shadow.

as a rounded mass with smooth outline simulating a lung neoplasm. However, when viewed along its length an interlobar effusion has a characteristic spindle or elliptical shape, lying in the position of one of the fissures, and with an entirely smooth margin that reflects its intrapleural location (Fig. 7.27). Such collections are most often seen in heart failure, their rapid disappearance with treatment earning them the name of ‘vanishing tumours’.

Difficulty may sometimes arise in distinguishing between an interlobar effusion in the lower end of the right oblique fissure and middle-lobe collapse. On the lateral view, an interlobar effusion bulges the fissures on each side while in lobar collapse the fissural edges are straight or slightly concave. On the anterior view also, middle-lobe collapse almost always obscures the right heart border while encysted fluid virtually never does so.

### Pleural calcification

The commonest causes of pleural calcification are following pleural tuberculosis, empyema and haemothorax and, in workers who have been exposed to asbestos, pleural plaques or diffuse pleural fibrosis. The pleural calcification following tuberculosis, empyema and trauma is more commonly unilateral than bilateral and may be extensive, encasing the lung (*lung en curasse*). Pleural plaques, which may be calcified or uncalcified, are more commonly bilateral and frequently involve the diaphragmatic pleura: when viewed end-on these may be seen as bands of calcification on the pleural surface; when seen *en*

**Fig. 7.27** Loculated effusion in horizontal fissure showing characteristic spindle shape.

*face* they simulate dripping candle grease or holly leaves beneath the rib cage. In diffuse pleural fibrosis associated with asbestos exposure, calcification is often bilateral and extensive (see Chapter 43).

## Solitary chest lesion

### Extrapulmonary lesions

The chest radiograph may reveal the presence and, with variable clarity, the characteristics of a solitary mass lesion. The first requirement in interpretation is to decide if the lesion is intrapulmonary or arises from pleura, chest wall, mediastinum or diaphragm, since the diagnostic possibilities are largely different for each. A lateral film usually localizes the lesion, although sometimes CT or other investigation is required if detailed characterization of the lesion is sought.

A lesion is intrapulmonary if it is projected in the plane of the lungs on each of two radiographs at right angles to each other and the entire margin is silhouetted by lung. The further characteristics of solitary nodules of pulmonary origin are described below.

A lesion of pleural origin, whether an encysted effusion or tumour, is seen on tangential view to have a broad base on the pleura of the chest wall, mediastinum or diaphragm and to have a smooth rounded or lobulated margin indenting the adjoining lung. Such findings may be seen in encysted pleural effusions (Fig. 7.27), benign tumours (e.g. fibromas) or malignant tumours (e.g. mesotheliomas, pleural secondary deposits). There is usually a small effusion at the costophrenic angle accom-

panying the D-shaped shadow of a loculated empyema. When viewed *en face*, pleural-based lesions may appear of relatively low density because they may be shallow, spreading out within the pleura rather than bulging the visceral pleura to any great extent. Typically also the lower margin of a 'hanging' pleural lesion indents, and is silhouetted by, the neighbouring lung to a greater extent than the tapering upper margin, so that the lower margin is more clearly defined than the upper.

Lesions of extrapleural origin have similar characteristics in profile and *en face* to the above, but it may be possible to establish their chest wall rather than pleural origin by noting abnormality of the adjacent ribs or extension of the swelling into the soft tissues of the chest wall. Thus an intercostal neuroma arising from one of the intercostal nerves may produce smooth pressure erosion of the inferior surface of the adjoining rib (Fig. 7.28), such smooth erosion being a manifestation of pressure change over a long period of time. In contrast, malignant primary bone tumours (e.g. sarcomas), blood-borne secondary cancer deposits in bone, lymphoma and plasmacytoma produce bone destruction that may be accompanied by an extrapleural extension of tumour with characteristics as described above. Haematomas due to rib fractures also give rise to extrapleural swellings. In assessing rib fractures, it should be noted whether the margins of the fractures are mineralized and clearly defined, as in simple fractures due to trauma or coughing, or are demineralized

and indistinct, with possible abnormalities of bone texture evident in ribs elsewhere, as in pathological fractures due to malignant bone disease. Certain lesions of extrapleural origin, such as lipomas, give rise to extrapleural shadows with no accompanying rib changes. CT readily demonstrates the low-density fat composition of a lipoma.

A mass of mediastinal origin is visible on an anterior radiograph when it causes a bulge in the normal mediastinal silhouette. As with masses of extrapleural origin, the margin of a mediastinal mass appears rounded and smooth where it abuts lung, any irregularities being smoothed out by the two overlying layers of pleura. A smooth swelling bulging from both sides of the mediastinal contour clearly has a mediastinal rather than pulmonary origin. If the mass produces a rounded swelling of one mediastinal contour only, it may be obvious from the visible portion of such a shadow that the mass is too large and too medially situated to lie in lung and must therefore have an origin in the mediastinum. It is often impossible to determine from an anterior radiograph whether a mediastinal mass is located in anterior, middle or posterior mediastinum. A lateral view is therefore mandatory since the range of diagnostic possibilities differs for these different compartments (see Chapter 49).

Primary lesions of the diaphragm, such as sarcomas, are rare; a much commoner problem is to determine the cause of a high or apparently high hemidiaphragm or portion of diaphragm. When confronted with such a problem, it is

**Fig. 7.28** Large intercostal neuroma associated with smooth erosion of lower border of fifth rib.

useful to consider in turn the structures from which such a shadow could arise (lung adjacent to diaphragm, pleura, diaphragm, subphrenic) and then to consider the pathological processes to which these could give rise (e.g. peripheral lung cancer, subpulmonary pleural effusion, tumour or eventration/paralysis of the diaphragm, diaphragmatic hernia). The features and diagnosis of a subpulmonary effusion as a cause of an apparent high diaphragm have been described above. Diaphragmatic paralysis is recognized on fluoroscopy or ultrasound: the entire hemidiaphragm moves sharply upwards on sniffing and inspiration. In eventration (weakness of the central tendon of the hemidiaphragm) the weak part also moves sharply upwards on sniffing but the margins of the hemidiaphragm usually move in a normal direction, so aiding differentiation from paralysis. Gas, faeces and fluid levels in bowel may be seen in the chest in a diaphragmatic hernia. In cases of doubt a defect of the hemidiaphragm can be further assessed by barium contrast studies, ultrasound or CT.

### Lung carcinoma

On the chest film lung carcinoma may manifest as the tumour mass itself, secondary collapse-consolidation from endobronchial obstruction by the tumour, pleural effusion, or spread giving rise to hilar and mediastinal lymphadenopathy, diaphragmatic paralysis or bone metastases. Lung carcinoma characteristically has a lobulated border, the margin often being spiculated from infiltration of tumour into surrounding lung. It may have a homogeneous consistency or be cavitated due to central necrosis. Such a cavity is usually eccentrically placed and the wall is of varying thickness, where areas of necrosis alternate with areas of continuing growth (Fig. 7.29). This continuing growth may give rise to a lobulated inner border, and the cavity wall typically remains of moderate average thickness (5 mm or more). The differential diagnosis in such cases is from other causes of cavitated lung lesions with walls of similar average thickness, most commonly lung abscesses and infarcts, and less commonly

**Fig. 7.29** Tomogram of large cavitating squamous carcinoma of lung: note the irregularity of the width of the cavity wall.

such conditions as rheumatoid nodules and Wegener's granulomatosis. Tuberculous cavities usually have rather thinner walls (2–3 mm), while the walls of bullae and staphylococcal pneumatoceles are of hairline thickness. Cavitated carcinomas are most commonly of squamous cell origin, either primary or secondary, but cavitation of tumours of other cell types does occur.

### Staging of lung carcinoma

CT is routinely used in the staging of lung cancer and assessment of operability. Dynamic scanning during infusion of intravenous contrast medium is performed to distinguish between normal hilar and mediastinal vascular structures and abnormal tissue from tumour extension. Such findings as mediastinal lymphadenopathy (Fig. 7.30) and unequivocal invasion of the chest wall may be shown. The role of CT in the staging process is as follows.

When CT shows an intrapulmonary tumour and no hilar or mediastinal lymphadenopathy, the patient may proceed directly to thoracotomy without the need for further staging by mediastinoscopy. More commonly, mediastinal nodes up to 1 cm diameter are seen on CT. Such nodes are considered normal since small reactive nodes are common in the general population. Although such small nodes may occasionally be malignant, the patient can again be offered surgery on the basis that preoperative biopsy of such nodes would necessarily be random with a very low chance of detecting malignancy.

CT does not distinguish malignant from inflammatory nodes; however, as a generalization, the larger the mediastinal nodes in patients with lung cancer, the more likely they are to be malignant. Nodes of 3 cm diameter are highly likely to be malignant but even at this size can

represent inflammatory reactive nodes, particularly in patients with pneumonia distal to a central tumour, in those people from areas of the USA in which histoplasmosis is endemic, or in dust-exposed workers in whom large anthracotic or silicotic nodes may be found. Patients cannot therefore be deemed inoperable solely by CT demonstration of enlarged mediastinal nodes; when such large nodes are detected the scan serves as a 'road map' for planning preoperative nodal sampling by mediastinoscopy, mediastinotomy or needle aspiration.

It is difficult to establish from CT whether a tumour is resectable when it lies in contact with vital mediastinal structures. A tumour is likely to be resectable (stage T3a or less) when less than 3 cm lies in contact with the mediastinum, it has less than a 90° circumferential contact with the aorta, or visible fat planes between it and vital mediastinal structures are preserved [13]. However, a contact with the mediastinum of greater than 3 cm or absence of visible fat planes does not necessarily imply inoperability and, since surgery offers the only chance of cure, exploratory thoracotomy should not be discounted in such situations.

MRI has few advantages over CT in the preoperative staging of lung cancer. It shows enlarged mediastinal nodes and is generally no more accurate in distinguishing between contiguity of tumour with the mediastinum and mediastinal invasion. However, it is superior in identifying involvement of major mediastinal blood vessels and has an advantage in superior sulcus tumours in showing extension to the brachial plexus and subclavian vessels.

### Other solitary lung masses

#### Solitary lung metastasis

A solitary pulmonary metastasis, radiologically simulating a primary lung carcinoma, is occasionally seen in patients with known current or pre-existing carcinoma or sarcoma or other malignancy. The diagnosis is suggested when biopsy of the lesion, by bronchoscopy, fine needle aspiration or other means, reveals tissue corresponding histologically with that of the known tumour elsewhere. More often such metastases are multiple and chest CT usually reveals further deposits that have not been seen on the chest radiograph. However, demonstration of further nodules subpleurally in the peripheral lungs and elsewhere requires cautious interpretation since these may represent coincidental granulomas. This is particularly the case in areas where histoplasmosis is endemic.

If chest CT shows no further lesions and resection is contemplated, it is advisable to examine also the regions of lymphatic drainage of the original tumour by CT, the liver by ultrasound or contrast CT, and to perform a radioisotope bone scan if there is any biochemical abnormality to suggest skeletal spread. Thorough preoperative

**Fig. 7.30** CT of bronchial carcinoma showing large mediastinal node (arrows) between bronchi and oesophagus.

investigation may spare the patient a fruitless attempt at curative resection when there is demonstrable dissemination elsewhere.

### Sarcoma

Primary sarcoma of lung is rare. The diagnosis is suggested by a rapidly expanding mass with a smooth well-defined border. Lung involvement in Kaposi's sarcoma, occurring particularly in patients with AIDS, is diffuse and therefore does not enter the differential diagnosis of patients with solitary mass lesions. The radiological changes of lung Kaposi's sarcoma are bilateral, ill-defined, nodular opacities or rather coarse linear or reticulonodular shadowing. These may be obscured by coincidental *Pneumocystis carinii* or other pneumonia. Pleural effusions and hilar and mediastinal lymphadenopathy may also be present in Kaposi's sarcoma [14].

### Tuberculoma

A tuberculoma, formed of caseous material, may be a manifestation of primary or postprimary tuberculosis. Tuberculomas are most commonly located in the upper lobes, are round or oval, measure 0.5–4 cm or more in diameter, and have smooth, sharply defined margins. They may contain flakes of calcification or may become heavily and almost uniformly calcified. 'Satellite' shadows, small nodules of tuberculous origin in lung adjacent to the tuberculoma, are present in up to 80% of cases, and these and the presence of calcification provide the main clues to the diagnosis.

### Hamartoma

This benign tumour characteristically has a very smooth well-defined margin, reflecting its indolent nature and slow growth, compressing surrounding lung without infiltration. Hamartomas are commonly less than 4 cm in diameter, though occasionally much larger, and growth may be observed on serial films, adding to the difficulty of differentiation from carcinoma. Calcification is present in approximately 25% of cases, the configuration of calcification being described as resembling popcorn (Fig. 7.31). The tumour is usually peripheral and rarely produces endobronchial obstruction, so that distal consolidation is unusual. Areas of contained fat as well as calcification may be evident on thin-section CT, further aiding the preoperative diagnosis [15].

Calcification, which takes time to develop, may be seen in tuberculomas and hamartomas, and usually indicates the presence of a non-malignant lung lesion. However, lung cancers may arise in areas of pre-existing scarring with calcification, so that the presence of calcification needs to be interpreted with caution.

**Fig. 7.31** Large smoothly rounded hamartoma with central 'popcorn' calcification.

### Carcinoid tumour

About 80% of carcinoid tumours are located centrally in major or segmental bronchi, and may present radiologically as the tumour mass itself or, more commonly, as distal collapse–consolidation due to the effects of endobronchial obstruction. When the tumour mass is visible, it is typically spherical or oval in shape with a smooth well-defined border. It is usually 1–4 cm in diameter but can be much larger, and visible calcification is exceptionally rare.

### Mycetoma

A chronic, commonly tuberculous, cavity may become colonized by *Aspergillus fumigatus* or other fungus, the mycelium presenting as an intracavitary fungal ball. An early sign of the presence of the fungus, sometimes visible before there is any change in the cavity itself, is of progressive thickening of the overlying pleura. The fungal mass forms an enlarging ball within the cavity, characteristically with a crescent of air separating it from the cavity wall

**Fig. 7.32** Large post-tuberculous cavity containing aspergilloma: large arrows indicate crescent of air; small arrows show cavitation within part of aspergilloma.

(Fig. 7.32). The fungal ball may itself become necrotic and cavitate, may develop calcification within it, or may discharge its contents into the bronchi with consequent reduction in size or complete disappearance. Recurrent or life-threatening bleeding may occur from the inflamed walls of mycetoma-containing cavities. Surgery is hazardous and carries a real risk of spread of infection to the pleural space; this complication can be managed by embolization of one or more of the feeding bronchial arteries.

## Hila

The normal hilar shadows are formed by the pulmonary arteries and veins only, as previously discussed. Since there are a wide range of normal diameters for the two measurable hilar arteries (the main pulmonary artery on the left and the basal branch of the pulmonary artery on the right), plain film recognition of moderate pulmonary artery enlargement is unreliable. However, in any one individual, changes in pulmonary artery size can be recognized on serial films (for instance, in cor pulmonale or due to vessel plugging in pulmonary embolism).

True hilar enlargement must be distinguished from apparent enlargement, caused by a mass or consolidation in lung in the plane of the hilum. This can usually be resolved in the PA view, as a hilar mass will distort and cause partial loss of the normal D-shaped hilar silhouette while a normal hilar outline will be maintained and projected through a lesion in the overlying lung. A lateral view resolves any uncertainty. It is sometimes difficult to decide if a hilum is enlarged or if an enlarged hilum is due to vascular enlargement, lymphadenopathy or a primary tumour at the hilum. This dilemma is most readily

resolved by contrast CT, which may also demonstrate unsuspected mediastinal lymphadenopathy.

If hilar enlargement due to lymphadenopathy is suspected, a decision should be made as to whether this is unilateral or bilateral, since this influences the differential diagnosis. Thus rounded or lobulated shadows from unilateral hilar, or hilar and mediastinal, lymphadenopathy are likely to arise from a condition affecting the ipsilateral lung. Common causes of this are tuberculosis in young people and lung carcinoma in the middle-aged and elderly. Bilateral hilar, or hilar and mediastinal, lymphadenopathy would most commonly suggest a different group of causes. Important in this group are sarcoidosis and lymphoma, which can both also present with nodular infiltrations in the lungs, and sometimes small-cell carcinoma and lymphatic spread of other malignancies, e.g. colonic carcinoma. However, bilateral hilar node enlargement may be seen as a manifestation of primary tuberculosis in Asian patients. A common practical problem is to determine if a young adult with such appearances has sarcoidosis or lymphoma. A lateral film can be useful, since evidence of marked lymphadenopathy in the anterior mediastinum favours lymphoma, while in sarcoidosis this is rarely seen radiologically although the anterior mediastinal nodes can be pathologically involved in this condition.

Hilar node calcification is usually due to healed tuberculosis. It may also occur in silicosis, where it often assumes an eggshell pattern (see Chapter 54); similar appearances may be seen in sarcoidosis (Fig. 7.33). It has recently been recognized that this may be a sequel to acute hilar node enlargement in individuals with high exposure to quartz [16]. Similar appearances may be seen also after hilar radiotherapy for lymphoma.

## Diffuse lung disease

The range of possible radiological changes in response to disease is limited. A specific diagnosis can rarely be made from the radiographic appearances alone in a patient pre-

**Fig. 7.33** Bilateral eggshell calcification of hilar nodes in a patient with quiescent sarcoidosis. (Courtesy of Dr James Choo-Kang.)

senting with diffuse lung disease. In most instances it is necessary to identify the pattern of radiographic abnormality and to consider the common causes for such appearances in the context of each specific clinical presentation.

In analysing a chest radiograph showing diffuse abnormality, it is necessary to determine the nature of the shadowing (e.g. nodular, reticular, ring shadows, line shadows or a combination), its distribution, its density (soft tissue or calcific), and whether there is involvement of extrapulmonary structures (e.g. rib metastases, hilar or mediastinal nodes). Further information may be provided by HRCT, the principles of which have been described above. The following is a summary of the main patterns of radiographic change and their commoner causes, although these sections are by no means exhaustive and are intended to serve as an introduction to which readers will add their own clinical experience.

### Nodular shadows

When nodular shadows are recognized, it is necessary to consider whether they are well defined or ill defined, their size range and their distribution.

In miliary tuberculosis the nodules are characteristically well defined, 3–5 mm in diameter and, as would be expected from their blood-borne origin, uniformly distributed throughout all three zones of both lungs (Fig. 7.34).

**Fig. 7.34** Uniformly distributed fine shadows of miliary tuberculosis.

Such appearances are also seen in other conditions, including sarcoidosis (when hilar and mediastinal lymphadenopathy may be present), blood-borne carcinomatosis, haemosiderosis and some types of pneumoconiosis, where the nodules tend to show relative sparing of the bases.

Widespread lung opacification, predominantly mid zone or mid and lower zone in distribution, in which nodular shadowing may be fluffier and less well defined than the above may be seen in atypical pneumonias (e.g. varicella, Fig. 7.35), pulmonary oedema and extrinsic allergic alveolitis. A particular diagnosis may be favoured by the presence of associated shadowing of other specific character (e.g. concurrent lymphatic lines in pulmonary oedema).

While some 80 causes have been described for diffuse shadowing produced by small nodules, the diagnostic possibilities diminish when larger nodules can be identified. Thus the nodules of miliary tuberculosis and haemosiderosis do not exceed an upper diameter of 5 or 6 mm. When multiple nodules of up to 1 cm diameter can be identified the commonest cause is carcinomatosis, although other conditions that may produce nodules of this size, generally of moderate number only and sometimes in clusters, include sarcoidosis, Caplan's syndrome and, in immunocompromised patients, fungal infection. With increasing size of lesion, the diagnostic possibilities reduce further. Multiple pulmonary masses of 3 cm diameter or more are usually due to dissemination of malignancy (metastases from carcinoma or sarcoma, Fig. 7.36), but other possibilities include fungal masses in immunocompromised patients, rheumatoid nodules, Wegener's

granulomatosis and progressive massive fibrosis in dust-exposed workers.

The lesions of progressive massive fibrosis are initially small but may enlarge to diameters of 8 cm or more (see Chapter 54). They are commonest in the upper and mid zones and may develop simultaneously yet asymmetrically on both sides. Initially, nodular shadowing due to simple pneumoconiosis is also visible; however, as the lesions enlarge and emphysema develops around them, these may become less obvious until only the fibrotic masses may be seen surrounded by emphysematous lungs. The lesions of progressive massive fibrosis are often irregular at first, although as they enlarge they tend to become oval or sausage-shaped, often with smooth well-defined lateral margins running roughly parallel with the overlying chest wall. Commonly peripheral at first, they migrate medially towards the hilum leaving grossly emphysematous lung between their surfaces and the chest wall (Fig. 7.37).

### Reticular shadowing

In fibrosing alveolitis, the predominant abnormality is characteristically fine reticular shadowing or, if coarser, a honeycomb appearance that is bilateral and maximal at the bases and periphery of the lungs (Fig. 7.38). Small nodules may be seen in conjunction with this reticulation, when the shadowing is described as reticulonodular, and there is often a ground-glass appearance that produces a haze in the affected basal regions. When the fibrosis is advanced, the adjacent heart border and diaphragm become indistinct and shaggy in outline, and the lung

volume diminishes. Appearances similar to fibrosing alveolitis occur in asbestosis, rheumatoid lung, scleroderma and due to treatment with many cytotoxic and other drugs.

A number of CT changes have been described in asbestos lung disease and fibrosing alveolitis. In addition to reticular and honeycomb shadowing, subpleural short lines (<2 cm long) may be seen reaching, and perpendicular to, the pleura (Fig. 7.39). These represent fibrosis in the interlobular septa and peribronchiolar fibrosis. Traction bronchiectasis may be seen in advanced interstitial fibrosis, representing bronchial dilatation due to traction

generated by neighbouring lung fibrosis and contraction (Fig. 7.40). Long, curved subpleural line shadows, parallel with and within 1 cm of the pleura, have been described but are non-specific and may be seen also in patients with normal lungs, where they represent bands of linear atelectasis. Areas of increased density in the dependent posterior parts of the lungs can represent true fibrosis or may be due to normal hypoventilation and gravitational blood flow, since they may disappear on rescanning the patient in the prone position.

In patients with asbestosis, calcified and uncalcified pleural plaques may be present, seen as local or extensive areas of pleural thickening up to about 5 mm thick, usually bilateral and commonly involving the diaphragmatic pleura as well as the pleura of the chest wall and mediastinal pleura. Coarse band shadows, 2–5 cm long, may be seen extending deeply into the lung along the connective tissue septa or bronchovascular bundles from the surface of plaques. Such band shadows may represent an extension of the pleural fibrotic process into the lungs rather than a primary fibrosis of the lungs.

Pleural adhesions and fibrosis may give rise to round atelectasis, most commonly seen in asbestos workers with pleural plaques but also arising occasionally in other instances of chronic pleural thickening (e.g. after trauma). Round atelectasis represents chronic collapse of a region of lung from hypoventilation beneath an area of rigid thickened pleura. The CT features are of a round, lens-shaped or wedge-shaped opacity in continuity with thickened overlying pleura, with the supplying pulmonary vessels sweeping into the margins of the mass to give a comet-tail appearance (Fig. 7.41).

Round atelectasis is commonest in the posteromedial lung bases, produces volume loss of the affected lobe and opacifies uniformly on contrast CT. The main differential

**Fig. 7.38** High-resolution CT of patient with fibrosing alveolitis showing well-developed bilateral fibrosis, most marked peripherally.

**Fig. 7.39** High-resolution CT of patient with fibrosing alveolitis showing strands of fibrosis extending perpendicularly from pleura into peripheral lung.

**Fig. 7.40** High-resolution CT in fibrosing alveolitis showing traction bronchiectasis caused by advanced honeycomb fibrosis.

diagnosis is from carcinoma, and the above features assist in the correct recognition of this benign condition. Consideration of the distribution of pulmonary fibrosis is important in differential diagnosis. The above-mentioned conditions are characterized by predominantly basal and peripheral fibrosis as described. In contrast, the fibrosis of chronic extrinsic allergic alveolitis occurs predominantly in the mid zones, with relative sparing of the apices and bases, and is mainly peripheral in distribution [17]. In the early stages of sarcoidosis widespread nodules and thickened interlobular septa may be present, while in the chronic burnt-out phase the fibrosis is predominantly central (in contrast to chronic extrinsic allergic alveolitis) in the upper and mid zones, with coarse honeycombing.

**Fig. 7.41** Round atelectasis in right paravertebral region: note underlying pleural fibrosis and calcification from asbestos exposure.

**Fig. 7.42** Tomography of extensive bilateral upper-lobe consolidation with cavitation (arrow) in postprimary tuberculosis.

### **Diffuse shadowing affecting particularly the upper lung regions**

In differential diagnosis the distribution of lung disease can be as important as the characteristics of any abnormal shadowing. Certain conditions that show preferential involvement of the upper regions of the lung deserve mention.

#### **Pneumonic infiltration at the apices**

A small number of conditions produce shadowing that simulates consolidation, sometimes with a visible air bronchogram, predominantly in the upper zones of one or both lungs. Of foremost importance is postprimary tuberculosis, which produces infiltrates particularly in the apical and posterior segments of the upper lobes and apical segments of the lower lobes. Cavitation within the areas of infiltration strongly support this diagnosis (Fig. 7.42). *Pneumocystis* may also present with unilateral or bilateral apical pneumonia (Fig. 7.43), also occasionally with cavitation (Fig. 7.44). Pulmonary eosinophilic pneumonia characteristically produces peripheral and apical infiltrations with sparing of the perihilar regions (Fig. 7.45), so that the radiographic appearance of this condition mimics the mirror image of pulmonary oedema, where the consolidation is central and perihilar. After radiotherapy to the supraclavicular nodes, most commonly 1–4 months after cessation of treatment, consolidation due to radiation pneumonitis may develop in the apices; this clears rapidly with steroid treatment but may progress to fibrosis with appreciable volume loss in the upper lobes.

**Fig. 7.43** Bilateral upper zone and right lower zone consolidation in *Pneumocystis* pneumonia.

#### **Fibroses affecting particularly the upper lobes and apices**

Linear or reticular scarring, with associated volume loss manifest by hilar elevation, tracheal deviation and crowding of the ribs is seen in the late or burnt-out stages of a number of conditions; in many instances there is no radiographic clue to the original causative disease. Fibrosis of this distribution is seen following tuberculosis, sarcoidosis, some forms of silicosis, radiotherapy to the lung apices as described above, in ankylosing spondylitis, sometimes in the late stages of asthma with bronchopulmonary aspergillosis, and following long-term use of the urinary

Fig. 7.44 Cavitation in *Pneumocystis* pneumonia.

Fig. 7.45 Peripheral consolidation characteristic of eosinophilic pneumonia.

antiseptic nitrofurantoin. The lung destruction may cause cavitation, and one or more cavities may in turn harbour an intracavitary mycetoma (see Fig. 7.32).

### Lymphatic (Kerley) lines

A careful search should be made on a chest film showing diffuse infiltration for lymphatic (Kerley) lines. Kerley A lines are seen as sharp line shadows (from hairline to about 1 mm in width and 1–3 cm long) lying midway between the hilum and lung periphery, and mainly point-

Fig. 7.46 Kerley A lines (arrows)

ing in the direction of the hilum (Fig. 7.46). Kerley B lines are similar thin line shadows, up to 3 cm long, that are seen peripherally and reach to the pleural surface at right angles to the chest wall (Fig. 7.47). Kerley A lines are produced by abnormally enlarged communicating lymphatics between bronchoarterial bundles and veins, and B lines by lymphatics in the interlobular septa. The importance of recognizing Kerley lines as a component of diffuse lung opacification is to limit the diagnostic possibilities. The most common causes are pulmonary oedema from cardiac insufficiency and malignant lymphatic infiltration (lymphatic carcinomatosis); in the one instance they represent lymphatic engorgement and perilymphatic oedema, and in the other malignant infiltration or lymphatic obstruction by proximal tumour. Kerley lines are also seen commonly in pneumoconiosis, where they represent interlobular dust deposition. A few hairlines simulating Kerley lines are seen rarely in pneumonia and sarcoidosis.

### Ring shadows

Multiple thin-walled ring shadows may be a recognizable finding on a chest radiograph showing diffuse disease. They are the cardinal sign of bronchiectasis and represent dilated bronchi seen end-on. They may be accompanied by parallel-line shadows representing the thickened walls of dilated bronchi viewed along their lengths, 'gloved finger' dense branching shadows produced by secretion-filled dilated bronchi, and loss of volume (manifest by crowding of lung markings in the affected region of lung),

Fig. 7.47 Kerley B lines.

hilar and mediastinal displacement and sometimes minor diaphragmatic elevation.

The chest radiograph in bronchiectasis may be normal, but if abnormal frequently underestimates the extent of the disease. HRCT is used for confirmation of the diagnosis and assessment of the extent of known bronchiectasis when a patient is being assessed for surgery. Dilated bronchi are recognized by a 'signet ring' appearance in which the diameter of the bronchus exceeds that of the neighbouring artery (Fig. 7.48). The lobar distribution of

Fig. 7.48 High-resolution CT showing ectatic bronchi in left lower lobe adjacent to cardiac border.

Fig. 7.49 High-resolution CT in Langerhans' cell histiocytosis (histiocytosis X) showing diffuse thin-walled ring shadows. Arrows indicate the granulomatous nodules that develop into cysts.

bronchiectasis is easily assessed by CT, although determination of the segmental involvement may be more difficult due to the anatomical distortion produced by bronchiectasis in affected neighbouring segments and lobes.

CT has replaced bronchography in the assessment of bronchiectasis, and there is currently no ideal bronchographic contrast agent on the market. In two studies comparing HRCT with bronchography, CT was highly sensitive and specific in confirming a diagnosis of bronchiectasis though somewhat less so in recognizing bronchiectasis at segmental level [18,19]. CT is therefore a

satisfactory and sensitive examination in confirming a diagnosis of bronchiectasis, and is appropriate for determining that a patient is unsuitable for surgery when widespread bilateral disease is shown. However, it is inferior to bronchography in demonstrating the segmental extent of bronchiectasis in patients who are considered suitable for surgery.

In cystic fibrosis the ring shadows of bronchiectasis are seen particularly in the upper lobes. Multiple thin-walled ring shadows may also be shown, particularly on CT, in Langerhans' cell histiocytosis (Fig. 7.49) and lymphangioleiomyomatosis.

# MINIMALLY INVASIVE DIAGNOSTIC PROCEDURES

DOUGLAS SEATON

This chapter describes a number of largely diagnostic procedures that have been found to be useful in the practice of respiratory medicine. The content is not exhaustive because some procedures that have diagnostic implications are discussed in other chapters and have been omitted from the text that follows. Diagnostic imaging is dealt with in the preceding chapter.

## Bronchoscopy

Endobronchial examination was first carried out in the last decade of the nineteenth century for the purpose of removing inhaled foreign bodies, and as long ago as 1904 a rigid bronchoscope with provision for suction and illumination came into use [1,2]. About 60 years elapsed before the fiberoptic instrument was introduced into clinical practice, being first passed through a rigid bronchoscope and later through a nasopharyngeal airway or directly through the nose itself [3–5]. The realization that these instruments could be used without the assistance of an anaesthetist soon led to their widespread uptake by respiratory physicians for a variety of diagnostic and, at a later stage, therapeutic purposes.

### Indications (Table 8.1)

#### Diagnosis of lung cancer

The commonest indication for bronchoscopy is to confirm or exclude a diagnosis of lung cancer. A small isolated episode of haemoptysis in a young non-smoker is likely to be due to acute bronchitis and need not lead to endoscopic examination [6]. However, young patients with haemoptysis who began smoking at an early age should be considered candidates for bronchoscopy, as should patients with haemoptysis in whom any of the following three criteria of increased risk are fulfilled: (i) age exceeding 40 years; (ii) intermittent haemoptysis lasting more than 1 week; and (iii) any abnormality on the chest radiograph [7]. A negative bronchoscopy in the presence of persisting

haemoptysis may lead to the need for high-resolution CT (HRCT) of the lungs to exclude a small area of otherwise occult bronchiectasis and also a competent examination of the nose and throat by an otorhinolaryngologist to exclude a source of bleeding in those areas that respiratory physicians tend to pass the bronchoscope through in the shortest possible time.

#### *Cough*

A persistent cough, without haemoptysis, in a previously well patient with chest radiographic features that are either normal or unsuggestive of neoplasm is usually due to some inflammatory cause, such as sinusitis, asthma, bronchial hyperreactivity following acute bronchitis, or gastro-oesophageal reflux. It should be possible to reach such diagnoses from the history, physical examination and non-invasive investigations, including lung function testing, without recourse to bronchoscopy in the great majority of patients; methacholine (or other bronchial challenge) testing and oesophageal pH monitoring is undertaken in selected cases [8,9]. When, despite the foregoing, no satisfactory explanation for an intractable cough can be found, bronchoscopy is indicated in order to exclude an underlying tumour, particularly if the patient smokes tobacco.

#### *Abnormal chest radiograph*

Bronchoscopy is also indicated when the chest radiograph is abnormal, showing either an opacity consistent with a lung tumour or changes suggestive of bronchial obstruction, such as the appearance of early volume loss or undoubted collapse, unresolved pneumonia or hemidiaphragmatic paralysis, raising the possibility of phrenic nerve involvement by tumour [10]. The physician should be reticent in ascribing volume loss to previous radiotherapy for carcinoma of the breast as these neoplasms may metastasize endobronchially, sometimes years later.

**Table 8.1** Principal uses of fiberoptic bronchoscopy.

---

<i>Diagnostic</i>
Diagnosis of lung cancer
Chest radiographic abnormality
Haemoptysis
Persistent or recurrent cough
Paralysed vocal cord
Positive sputum cytology
Staging of lung cancer (see Chapter 41)
Diagnosis of diffuse lung disease
Identification of infecting agents
Immunocompromised host
Immunocompetent host
 <i>Therapeutic</i>
Insertion of endotracheal tube
Tamponade for bleeding*
Foreign body removal*
Aspiration of secretions*
Relief of tracheobronchial obstruction
Laser therapy
Insertion of stents
Brachytherapy

---

\* May be better carried out with rigid-tube bronchoscope.

### ***Vocal cord paralysis***

The finding of a paralysed vocal cord calls for careful endoscopic inspection of the bronchial tree, whether or not posteroanterior and lateral chest radiographs are normal [11]. Normal bronchoscopic findings may need to be followed by CT examination of the mediastinum, extending up to the neck in order to follow the course of the corresponding recurrent laryngeal nerve. The vocal cord palsy may be regarded as idiopathic once these investigations have been completed with negative results.

### ***Positive sputum cytology***

Occasionally expectorated sputum is found to contain neoplastic cells on cytological examination even though the chest radiograph itself provides no clear localizing features [12]. The oropharynx and larynx should be examined by an otolaryngologist in such cases, as the cells have been picked up by sputum *en passant*. If this examination is normal, bronchoscopy may find tumour, usually squamous cell carcinoma, that is often central, although the author has also seen peripheral lesions develop in this situation. When bronchoscopy is negative it is usual practice to repeat the examination at 3-monthly intervals. For several years some workers have advocated a meticulous examination of the bronchial tree down to subsegmental level with a small-diameter endoscope and the application of fluorescent bronchoscopic techniques using intravenous substances (such as haematoporphyrin derivative) that may be taken up by tumour and which fluoresce

under an appropriate light source, although the technique has not yet reached the stage of widespread practical application [13,14].

Even when a clinical diagnosis of lung cancer is virtually certain in terms of radiographic and other findings, bronchoscopy is still indicated, unless the patient is *in extremis*, in order to obtain histological confirmation of whether the tumour is primary non-small-cell or small-cell lung cancer or metastatic and to assist in the process of staging (see Chapter 41). Without this information, the good ship 'clinical conviction' will sometimes founder on the rocks of reality!

### **Diagnosis of diffuse lung disease**

Transbronchial lung biopsy, carried out through the fiberoptic bronchoscope, is one of a number of possible methods by which lung tissue may be sampled, and the respective merits of this technique compared with various forms of needle, trephine, thoracoscopic or open biopsy are discussed later.

The decision about whether an invasive procedure such as transbronchial lung biopsy should be used has to be weighed up in terms of risk and benefit. The risks are well known and are spelt out in a section that follows. Although relatively small, they may be unjustifiable when the diagnosis can be made with near certainty without histology. Sarcoidosis is sometimes a case in point when it presents with a diffuse pulmonary infiltrate occurring in an asymptomatic, immunocompetent patient with bilateral hilar lymphadenopathy, absent crackles on auscultation and normal measurements of lung function. Histological confirmation could be obtained several weeks later and without risk to the patient by means of a Kveim test. On the other hand, the same disease may present with an identical pulmonary infiltrate without hilar lymphadenopathy in a patient with an impaired gas transfer factor and worsening exertional dyspnoea. Therapeutic action is then urgently called for and diagnostic confirmation cannot wait. Although an argument can be made for the 'blind' use of corticosteroid therapy in such situations, in that the prognosis of many such diffuse lung diseases is related more closely to response to steroids than to histological appearance, it is nevertheless standard practice to obtain tissue in these circumstances, a procedure likely to put the diagnosis on a firm footing and that should at the very least avoid the unusual but potentially disastrous confusion of sarcoidosis with miliary tuberculosis.

The specimens obtained by transbronchial lung biopsy are necessarily small and the diseases that lend themselves best to diagnosis by this technique are those with a highly characteristic histological pattern that is repeated diffusely throughout the lungs so that there is little room for sampling error. These include relatively common

conditions such as sarcoidosis and lymphangitis carcinomatosa and rarer conditions such as eosinophilic pneumonia and pulmonary alveolar proteinosis, the latter being characterized by the finding of a strongly eosinophilic and typically periodic acid–Schiff (PAS)-positive granular material. Lymphomatous or leukaemic infiltration is less easy for the histologist to identify on small biopsies but may sometimes be suggested. Appropriate staining may also identify particular pathogens, such as *Pneumocystis carinii* in the immunocompromised host (see Chapter 52) or mycobacteria in the caseating granulomas of miliary tuberculosis.

Small transbronchial samples may be insufficient to establish a definite histological diagnosis in diffuse lung disease such as cryptogenic fibrosing alveolitis (interstitial pulmonary fibrosis). The material sampled in such cases may be found to contain non-specific inflammatory or fibrotic changes that may be described by the histologist as being 'consistent with' rather than 'diagnostic of' fibrosing alveolitis. Such a report may provide little additional practical information as the clinician may well have been able to reach such a provisional diagnosis on the basis of the history, physical signs, lung function findings and the result of HRCT of the lungs, and these patients would be likely to receive treatment with a trial of high-dose corticosteroids anyway. A larger piece of tissue is diagnostically more reliable than transbronchial biopsies in providing a definitive diagnosis in such conditions where the histology may be either 'difficult' on a small sample or distributed in a patchy fashion, so that sampling error may occur. Open or thoracoscopic lung biopsy may therefore be of greater value in cryptogenic fibrosing alveolitis if histology is considered essential, although often it is not and in each centre the expertise and interests of local personnel are likely to be important factors in determining the most appropriate diagnostic route [15–17].

Some, but not all, transplant centres use so-called 'surveillance bronchoscopy' with transbronchial lung biopsy in order to detect the development of obliterative bronchiolitis in lung transplant recipients [18,19].

### Identification of infectious agents

The fibreoptic bronchoscope may be used to obtain microbiological evidence of lower respiratory tract infection by the examination of (i) aspirated bronchial secretions, washings or lavage fluid, (ii) endobronchial brushings or (iii) transbronchial lung biopsies. Other techniques, of varying degrees of invasiveness, used to sample the lower respiratory tract for evidence of infection include percutaneous needle or trephine biopsy of the lung, open or thoracoscopic lung biopsy, and transtracheal aspiration. The place of each different approach is considered later in this chapter. It is stressed that most bacterial infection of the lung can be treated without recourse to such procedures,

antibiotics being selected empirically on the basis of probability with possible modification in the light of response or subsequent microbiological data (see Chapter 13).

Such empiricism is more likely to fall down in patients whose immune systems are compromised by coexisting disease. Peculiar difficulties are created in this group by the wide variety of unusual organisms that may be responsible for pneumonic infection, which commonly defy diagnosis by ordinary means and may therefore elude effective treatment unless special efforts are made to identify the responsible microbes. One such opportunist is the fungal organism *P. carinii*, which may be successfully diagnosed by fibreoptic bronchoscopy using bronchial lavage, transbronchial biopsy with touch preparations and bronchial brushings, these procedures demonstrating cysts in bronchial secretions or lung tissue (see Chapter 52) [20,21]. These methods may yield positive results in patients with AIDS even if the chest radiograph is normal, and it has been recommended that efforts to confirm the diagnosis should be made in such patients when symptoms suspicious of respiratory infection are accompanied by a fall in the single-breath carbon monoxide transfer factor, a low  $\text{SaO}_2$  on exercise and an increased alveolar–arterial oxygen gradient [22,23].

Cytomegalovirus (CMV) may also be detected by transbronchial lung biopsy in immunocompromised subjects either by the demonstration of intranuclear and intracytoplasmic inclusion bodies in lung tissue or by the culture of CMV from lung tissue [22]. A wide variety of other organisms may be isolated from bronchoscopic sampling using appropriate microbiological techniques, including *Mycobacterium tuberculosis*, atypical mycobacteria and fungi [22]. Invasive aspergillosis has been diagnosed following examination of lavage or transbronchial lung biopsy material, although definite confirmation sometimes requires an open or thoracoscopic procedure [24–26]. Coccidioidomycosis is also detectable by transbronchial lung biopsy [27]. Tuberculosis may be diagnosed in patients who are not producing sputum by direct smear or culture of material obtained from bronchial brushings, transbronchial biopsy or bronchial lavage fluid [28,29]. The finding of more usual bacterial pathogens must be treated with caution as these may be picked up from the nasopharynx during the passage of the bronchoscope, as has been shown in normal volunteers [30]. Techniques have been developed in which the bronchoscopic brush is protected in order to avoid such contamination [31]. Microbiological aspects of sampling via the bronchoscope are discussed in a later section.

### Bronchoalveolar lavage

The fibreoptic bronchoscope acts as a suitable conduit for the injection and aspiration of saline in bronchoalveolar lavage (BAL), a procedure discussed later in this chapter.

## Bronchography

The fiberoptic bronchoscope became useful as a means of facilitating bronchography in patients in whom bronchiectasis (see Chapter 28) was suspected. It had the advantage of permitting more selective application of contrast medium than could be achieved by other methods [32,33], but has been superseded by HRCT of the lungs, following which propylidone has been withdrawn from the market. Although bronchography is still possible with contrast media such as Iotrolan 300 [34], it is now rarely performed.

## Therapeutic applications

Although primarily used for diagnostic purposes, fiberoptic bronchoscopy has a number of therapeutic applications.

- 1 Insertion of an endotracheal tube for general anaesthesia in patients in whom extension of the neck may be dangerous (e.g. atlanto-axial subluxation in rheumatoid disease), the tube being 'piggy-backed' over the flexible bronchoscope once it has been inserted [35].
- 2 Tamponade of endobronchial bleeding, either with the end of the bronchoscope itself or by using a Fogarty or other purpose-designed balloon catheter (see below) [36].
- 3 Removal of foreign bodies [37,38].
- 4 Aspiration of secretions in acute inflammatory lobar atelectasis where physiotherapy has proved unsuccessful in achieving this end [39]. It has to be said that the rigid bronchoscope is better suited to the last three applications as a result of its stronger suction capability and the fact that its large channel also permits the easier removal of inhaled foreign bodies and the packing of a bleeding bronchus under direct vision [40].
- 5 Relief of tracheobronchial narrowing by:
  - (a) laser treatment, which may be administered through the channel of a fiberoptic or rigid bronchoscope in the palliative treatment of lung cancer (see Chapter 41), this having been reviewed elsewhere [41,42];
  - (b) placement of stents [43,44]; and
  - (c) delivery of endobronchial radiotherapy, a technique known as brachytherapy [45,46].

Although external beam radiation is usually brought to bear for the palliative relief of symptoms caused by malignant involvement of the trachea or a large bronchus, this is not always possible as the narrowing may be critical so that any additional oedema after treatment may make a bad situation worse. In this predicament the options that may be available to the physician include (i) the abandonment of resuscitative measures and the use of morphine, (ii) the temporary use of a low-density helium-oxygen (4:1) mixture to reduce the work of breathing, or (iii) intervention by an expert in surgical disobliteration (e.g. diathermy resection), stenting, laser treatment or

brachytherapy. A number of large centres are becoming experienced in treating this difficult group of patients by a combination of these measures [47] and the results of controlled trials of one regimen versus another may yet be forthcoming [41].

Patients who have been stented require close follow-up and are likely to require repeated bronchoscopies. Stents may become obliterated by inspissated respiratory secretions, granulation tissue or continued growth of tumour and they occasionally migrate or erode through the tracheobronchial wall. Wire stents are usually 'permanent', whereas those that have an external siliconized plastic surface are potentially removable and replaceable. The accurate placement of stents may be undertaken by an experienced thoracic surgeon using the rigid bronchoscope and general anaesthesia [48], although expandable metal stents are being inserted with increasing frequency by physicians using local anaesthesia [49].

Surgical disobliteration or laser therapy may produce rapid palliation of the effects of large airway narrowing, although not without risk. However, neither approach can be used if the narrowing has arisen as a result of extrinsic compression or if the problem is one of an intramural 'shelving down', in which case stenting or brachytherapy may be more appropriate, the latter treatment having some effect on extramural tumour but being slow in delivering benefit, the response taking about 1 month. Brachytherapy itself carries a risk of fatal haemoptysis, the average figure from the literature being about 8% [41].

## Procedures for fiberoptic bronchoscopy (Table 8.2)

Having determined an indication for bronchoscopy, the patient's consent is obtained. This is more likely to be forthcoming if a reassuring explanation of the painless nature of this routine examination is given in terms that the patient will understand and if questions are invited. Such verbal explanation may be reinforced by a sensitively worded written pamphlet, the contents of which the patient may read at leisure. Bronchoscopists who hand out such leaflets without having read them themselves for a

Bronchoalveolar lavage

decade or more are occasionally embarrassed when the patient subsequently points out a deviation from the script.

Most bronchoscopies are carried out electively on a day-case basis, the patient being asked not to eat or drink for 4–6 h beforehand, so that for an afternoon procedure a light breakfast is permissible. Advance provision must be made to get patients home safely as the law is unlikely to regard them as being capable of safe driving if they have received sedative medication.

### Supplemental oxygen

It is usual to give the patient supplemental oxygen via nasal cannulae and to monitor the saturation by pulse oximetry. If it is decided, at an earlier assessment, that a high concentration of inspired oxygen is likely to be needed, this can be achieved using a high flow mask with a reservoir bag, a hole having been made in the front of the mask beforehand using a leather punch or other suitable tool. The patient can then breathe high-flow oxygen through nasal cannulae while the instrument is being passed, after which the reservoir mask may be 'rail-roaded' down the shaft of the instrument and into place on the patient's face.

### Premedication

Intramuscular atropine is usual, although its use has been based more on long-standing practice than substantiated evidence of clinical benefit, so that its routine application has been questioned [50]. The traditional adult dose is 0.6 mg. The anticholinergic action of atropine may reduce secretions in the airways as well as diminishing the chance of reflex vasovagal phenomena such as bronchoconstriction and bradycardia [51].

### Sedation

Most bronchoscopists give their patients sedation [52], although whether this is necessary has been the subject of debate for many years [53,54]. Morphine (half-life about 2.5 h) may be given 20–40 min before the procedure in order to produce a sense of euphoria, reduce anxiety and suppress coughing. The standard adult dose is 10 mg intramuscularly, although this may be reduced to 5 mg in small or elderly patients.

Other advocates of narcotic agents prefer the short-acting opiate alfentanil (half-life about 1.5 h) [55], this being given intravenously either before or after the application of topical anaesthesia to the upper respiratory tract [56]. Some studies suggest that this agent is a better cough suppressant than other sedatives, including intramuscular morphine (as papaveretum) [57], intravenous diazepam (as Diazemuls) [57] and midazolam [58].

Many bronchoscopists prefer to use an intravenous benzodiazepine [52]. As well as sedating, these compounds produce an amnesic effect that, paradoxically, may be greater when the more rapidly metabolized midazolam (half-life about 2.5 h) rather than diazepam (half-life about 20 h) is used [59]. It should be borne in mind that this effect may prevent the patient from retaining information given after the bronchoscopy has been completed. One practice is to give 2.5 mg midazolam by slow intravenous injection over about 30 s (1 mg for those aged over 70 years), giving further small increments after 1–2 min until the patient feels drowsy. Diazepam, being half as potent [60], may be given as an alternative in similar fashion at about twice the dose, i.e. 5 mg initially for the younger and 2 mg for the older patient. An average total dose for midazolam in a younger patient might be about 5 mg and for diazepam 10 mg, although requirements are variable and some bronchoscopists use high doses to produce complete amnesia [60,61]. One group found that 2 mg lorazepam taken orally 1.5 h before bronchoscopy reduced the patient's perception of the unpleasantness of the procedure the next day compared with placebo [62].

Any sedative is better omitted altogether if the forced expiratory volume in 1 s ( $FEV_1$ ) is less than 1 L, if the  $Paco_2$  is raised, or indeed if the patient's respiratory function gives any cause for concern. It is common experience that elderly patients tend to display greater equanimity when subjected to bronchoscopy than do some young adults, who as a group may be more likely to benefit from sedation. It is the author's practice not to sedate any patient routinely but to offer sedation to patients under the age of 65 years if their ventilatory capacity is near normal. It is as well to be more selective in other groups and to omit sedation altogether in the very elderly and frail patient. Extreme caution is advised if sedation is given to elderly patients and it should always be remembered that it is entirely possible to carry out fiberoptic bronchoscopy without any sedation at all [53,63], many patients responding adequately to the explanation and reassurances of an experienced operator and the endoscopy staff.

Should respiratory depression occur with any of the opioids, their effect can be rapidly antagonized by 100–200 µg of naloxone hydrochloride as an intravenous bolus repeated with 100 µg every 2 min until the desired response is achieved. Up to 10 mg may be given safely but such high doses are unlikely to be necessary and, if approached, another cause for the patient's condition should be considered. The half-life of naloxone is 60–90 min and patients who have responded should continue to be closely monitored if a longer-acting opiate has been used [64].

The benzodiazepines are effectively antagonized by intravenous flumazenil, the usual dose being 300–600 µg. It has a short half-life of about 1 h so that it may also need

to to be repeated if resedation develops [64], being given as 200 µg over about 15 s initially, thereafter at 100-µg dose increments at 1-min intervals to a maximum of 1 mg. Flumazenil itself may produce feelings of nausea and agitation [65].

Withdrawal reactions may occur if either of these antagonists are used in patients who are chronic takers of opiates or the more commonly prescribed benzodiazepines. Some endoscopists use antagonists routinely at the conclusion of their examination [66]. Adequate endoscopy staff levels are essential if patients who have received sedation are to be adequately monitored while recovering from bronchoscopy and proper facilities for resuscitation should be readily available.

### Topical anaesthesia

The great advantage of fiberoptic bronchoscopy is that it can be carried out under topical anaesthesia. In earlier days rigid bronchoscopy was similarly applied, this being an unforgettably unpleasant procedure for most patients and one that is nowadays obsolete.

A 10-mg benzocaine lozenge may be given to the patient to suck at the time of premedication. About 20–40 min after premedication the patient is usually transferred to a couch, although the procedure may be carried out equally well in a hospital bed from which the head has been detached. The patient is propped comfortably in a semi-recumbent position by means of a foam wedge and/or pillows. Many operators prefer to work from the front as this enables them to talk to their patient more comfortably. Those who prefer to pass the instrument standing behind the patient find it easier if the patient is relatively flat, sup-

ported by only two pillows. An adjustable fluoroscopic table is needed if X-ray screening is to be used.

There are various ways in which the topical anaesthetic may be delivered. One method is to spray a 4% lidocaine (lignocaine) solution into both nostrils using an atomizer, with the advice to the patient to 'sniff it back' and a warning about its foul taste. Alternatively, the nasal mucosa may be anaesthetized with 2% lidocaine gel containing 20 mg/mL, about 5 mL being applied directly from the tube into each nostril (200 mg) using the conical applicator supplied by the manufacturer; there is some evidence to suggest that this is less unpleasant for the patient [67] and that plasma levels may be lower when the gel is used [68].

A 4% lidocaine solution may also be sprayed directly into the patient's mouth in the direction of the fauces. The patient is then asked to say 'aaah' in order to elevate the soft palate and two or three metered-dose sprays of 10% lidocaine (20–30 mg) may be directed at the cords using a removable and sterilizable angled nozzle (Fig. 8.1). An accurate aim usually produces coughing, at which point the spray is rapidly withdrawn from the mouth. It is the author's practice to further anaesthetize the cords and upper respiratory tract with about 5 mL of 4% lidocaine solution (200 mg) given by transcutaneous cricothyroid injection. The cricoid cartilage is usually easily palpated by the operator's forefinger with the patient's neck slightly extended, it being the first prominence above the cartilagenous tracheal rings. Immediately above it and below the next prominence, which is the thyroid cartilage, is a shallow depression that marks the cricothyroid membrane. This area is wiped with an alcohol swab and the patient warned that 'the voice box is going to be numbed'.

**Fig. 8.1** Some equipment used in fiberoptic bronchoscopy. Left to right: atomizer (local anaesthetic), bite block, lidocaine metered-dose spray with angled nozzle, slides and screw-top jar for fixative, specimen trap for suction line.

The patient is requested not to swallow (in order to avoid movement of the larynx) and warned that coughing is likely but is asked to try to hold the cough for a few seconds. The patient is then asked to 'lift up your chin and look at the ceiling' in order to achieve extension of the neck and a 23-gauge needle attached to the loaded syringe is smoothly inserted in the midline. If correctly positioned it will meet no resistance and withdrawal of the plunger will be rewarded by bubbles of air indicating a proper intratracheal position. The local anaesthetic is then injected as rapidly as possible. A small proportion of patients can contain their cough until the syringe has been emptied but most cannot. As soon as the cough occurs the needle is rapidly withdrawn to avoid trauma. If less than 3 mL has been injected, then the remainder can be injected by reinserting the needle, coughing being less frequent with the second application. Many bronchoscopists prefer to anaesthetize the cords under direct vision from above while advancing the bronchoscope ('spray as you go'), while others have delivered the lidocaine using a nebulizer and pump [69]. Any of these methods is satisfactory and a matter of personal preference; in the author's experience, cricothyroid anaesthesia is the least unpleasant for the patient and there is some evidence to suggest that it results in less patient discomfort and coughing [70,71].

Serious adverse effects from the use of lidocaine at bronchoscopy appear to be unusual but it should be used sparingly as epileptic seizures have been reported [72]. The safe dose for infiltration is said to be 3 mg/kg [64], although much higher levels than this were routinely used topically according to a survey of British bronchoscopists [52], the average dose given being about 350 mg. A significant quantity is presumably removed through the suction channel of the bronchoscope. That which is not is absorbed from both mucosal surfaces and the gut, in which case first-pass metabolism occurs in the liver. Absorption is particularly rapid from the lower respiratory tract, the pharmacokinetics at this site apparently approaching that following intravenous administration [72]. Peak levels may occur up to 1.5 h after its use and toxicity may occur at plasma levels of 5 µg/mL or more [64]. The amount of lidocaine used should be kept to a minimum in patients with liver disease [72]. Topical cocaine solution, although a good anaesthetic agent, is less commonly used than lidocaine and is more likely to produce cardiovascular side-effects, including dysrhythmias [73,74].

### Passing the bronchoscope

Having anaesthetized the upper respiratory tract, the shaft of the bronchoscope is well lubricated with 2% lidocaine gel and is advanced into a nostril under direct vision, being passed along the floor of the nose through the

widest visible opening between the turbinates, which project inwards from the lateral margin of the nasal cavity. Gentle pressure is all that is required if the space is adequate and the instrument should never be forced. If the bronchoscope does not advance easily it should be withdrawn and the other nostril tried. In a significant proportion of patients, the nasal approaches are too narrow to permit the bronchoscope to pass, in which case the patient is asked to hold a bite block (see Fig. 8.1) between the teeth or gums and the instrument is introduced into the oropharynx through it. It is necessary for the bronchoscopist's assistant to gently hold this in place with two fingers spread on either side of the orifice in order to avoid damage to the shaft should the bite block become displaced, which might allow the patient to bite directly into the bronchoscope. As the instrument is advanced, the tip is flexed downwards and the epiglottis and larynx come into view (Fig. 8.2). The position and movement of the vocal cords with respiration is noted and the patient is asked to say 'eeee', so that full apposition of the cords can be observed and vocal cord paralysis confirmed or excluded.

A unilateral paralysed cord lies in an 'intermediate' position and does not fully adduct. The left cord is involved more often than the right because of its longer course through the mediastinum. Involvement of the right recurrent laryngeal nerve by tumour implies that the lesion extends into the neck. Lung cancer is the commonest cause in respiratory practice but a diagnosis of idiopathic vocal cord paralysis [75] is sometimes reached following normal bronchoscopy and negative radiographic procedures, including CT of the mediastinum and neck. Bilateral vocal cord paralysis produces a narrow glottic chink and laryngeal stridor, usually occurring as a

Fig. 8.2 Bronchoscopist's view of the larynx.

complication of previous thyroid surgery [75]. Stridulous inspiratory noises are also sometimes produced by patients with 'functional upper airway obstruction' [76,77]; more rarely sarcoidosis of the upper respiratory tract may produce this symptom, sometimes involving the epiglottis and laryngeal structures but usually sparing the cords [78]. The author has seen a case of bilateral vocal cord palsy occurring in association with rare neuromyopathic disease.

The tip of the bronchoscope is centred with regard to the vocal cords and quickly advanced through the opening during inspiration. The tip should not be forced through and if the cords appose it should be withdrawn and further attempts made. Additional 2.5-mL aliquots of 2% lidocaine (50mg) may be instilled down the suction channel of the bronchoscope if needed, using boluses from 5-mL syringes made up to volume with air in order to allow for the instrument's dead-space and to rapidly empty all the local anaesthetic from its channel. The passage of the bronchoscope through the vocal cords is one of the least pleasant parts of the procedure, and a transient sensation of apnoea, about which patients may be forewarned, is common.

Some bronchoscopists have preferred to use the oropharyngeal rather than the nasal approach and introduce an endotracheal tube 'piggy back' over the bronchoscope once the trachea has been entered [79]. This method has the principal advantage of allowing removal of the bronchoscope so that the tip can more easily be cleaned if vision becomes obscured by tenacious secretions.

Once the cords have been passed any further lidocaine is given through the suction channel as 2% solution. If cricothyroid local anaesthesia has been used, there is usually little further coughing other than when the tip of the bronchoscope is manoeuvred into the upper lobes before which additional local anaesthetic does not go amiss. The local anaesthetic action of lidocaine is about 20 min and allowance of a safety margin of 1 h after bronchoscopy is quite long enough, after which the fully awake patient's craving for a cup of tea may be satisfied.

#### **Further advancement of the instrument and endoscopic appearances**

A good appreciation of normal and abnormal endoscopic appearances can be gained by logging sufficient 'flying hours'; however, even with experience the distinction between likely benign and malignant change is not always clear and is subject to error. Atlases of bronchoscopic appearances that contain clear images have been published [80] and are helpful as they accurately document the appearances of some of the rarer conditions with names designed to impress colleagues, such as tracheo-bronchopathiaosteochondroplastica. Such conditions are

infrequently encountered and might give rise to confused wonderment if not seen before.

It is also all too easy, even for an experienced bronchoscopist, to lose his or her bearings during the course of an examination, particularly in the more distal reaches of the bronchial tree, and there is no disgrace attached to the deliberate withdrawal of the instrument back to a familiar landmark, such as the carina, in order to reorientate. Vision not uncommonly becomes obscured by mucus or blood on the end of the instrument. This may be removed by flexing the end of the bronchoscope and wiping it on the membranous part of the tracheal wall or by injecting 5 mL normal saline down the channel. It is rarely necessary to withdraw the bronchoscope to wipe the end.

#### ***Trachea***

This is sometimes surprisingly tortuous in the elderly, often being bowed in from the left by the aortic arch, which runs its course anterior to the carina before looping round the lateral aspect of the lower third. The first third of the trachea is extrathoracic. It is as well for the beginner to remember that the endoscope is a solid 'space-occupying lesion' and not be tempted to pass it through a trachea that is grossly narrowed by disease or indeed to biopsy tracheal lesions that are causing a significant stenosis in case they become oedematous and cause the narrowing to become critical.

The trachea may be involved by primary neoplastic disease. All of these tumours are unusual and most are malignant, squamous carcinoma probably being found most frequently, followed by adenoid cystic carcinoma (formerly known as cylindroma), and less frequently carcinoid tumour, adenocarcinoma and small cell carcinomas. Benign tracheal tumours are even more rare and include papillomas, neurofibromas, neurilemmomas and leiomyomas. Direct spread of malignant disease to the trachea from elsewhere is more common and this may occur from mediastinal lymph nodes, lung, thyroid and oesophagus. Inflammatory narrowing may result from the trauma of endotracheal intubation and tracheostomy may also produce stenoses.

Non-neoplastic tracheal pathologies are rare and include Wegener's granulomatosis, which may cause subglottic stenosis [81,82], and tracheal amyloidosis [83,84]. Isolated, pale, almost pearl-coloured cartilagenous spurs or projections are not uncommon especially in the elderly and they defy attempts at biopsy, as do the remarkable stalactite- and stalagmite-like projections of tracheo-bronchopathia-osteochondroplastica, which continue down beyond the carina [85]. The trachea may be narrow in the transverse diameter, as in the so-called 'inverted-U' normal variant, but in relapsing polychondritis may be excessively narrow, assuming the slit-like appearance of the inside of a scabbard [86].

### *Tracheobronchial mucosa*

This is normally smooth and pink, and the main carina and subcarinae (bronchial or segmental spurs) are usually sharp. The more recent generations of fiberoptic bronchoscope provide excellent vision and a high degree of tip manoeuvrability so that all numbered segmental bronchi (see Fig. 8.3) may be inspected or even entered with little difficulty. The right upper lobe bronchus arises much sooner and usually more acutely than its opposite number on the left, so that the beginner often passes its orifice unawares. Once entered, three segmental bronchial openings can usually be identified without much difficulty. The acute angulation required to enter either upper lobe often causes patients to cough, despite the application of local anaesthetic, and it is considerate to forwarn them of this just before undertaking the manoeuvre. An accessory right upper lobe bronchus occasionally arises from the distal trachea. The tyro may be surprised by the relatively small diameter of the middle lobe bronchus as it arises anteriorly, directly opposite and not much wider than the apical (superior) segmental bronchus of the right lower lobe. The left upper lobe is easier to enter, the lingular division bronchus presenting itself first, greater angulation being required to enter the upper division bronchus. The apical segment of the lower lobe on the left is also easily identified. The basal segmental bronchi on both sides are easy to inspect and the novice will soon cease to be distracted by their variable anatomy.

Inflammation is indicated by areas of mucosal reddening and by mucosal oedema with resultant blunting of interlobar or intersegmental spurs. There may also be increased production of mucus and mucosal gland ducts may be prominent as visible 'mucous pits' in the bronchial wall. Suppurative lung disease may be marked by purulent endobronchial secretions, which may be sucked out more easily if a larger channel instrument is being used. Despite the fact that histological evidence of endobronchial disease is common in sarcoidosis, having been reported in 20–70% of cases [87], visible nodular 'cobblestone' or infiltrative changes are seen much less frequently, although these are occasionally very evident and bronchial stenoses may also be produced [88]. Fungal infections, such as invasive aspergillosis or candidiasis, may produce diffuse infiltrative mucosal changes in immunosuppressed patients, the former characterized by necrotic change [89], the latter by a 'white carpet' appearance. Florid endobronchial involvement has been documented in histoplasmosis [90]. Tuberculosis may also unusually produce florid endobronchial inflammatory appearances that may mimic tumour [91,92]. Endobronchial changes due to tuberculosis, comprising hyperaemia, caseating masses and the protrusion of extra-bronchial lymph nodes, may also be seen in patients infected with human immunodeficiency virus (HIV) [93].

Neoplastic changes are variable in appearance. A centrally placed tumour may be clearly visible as an endobronchial mass of tissue that may partially or totally occlude the lumen in which it is situated. Such lesions may be smooth-walled or more irregular and cauliflower-like. Occasionally they arise from a stalk, the base of which may be impossible to locate. They may be a pinkish colour or may be covered by white or grey material, biopsies of which may reveal only necrotic slough. A similar slough-like appearance may be produced by large mucous plugs that are sometimes found occluding a bronchial orifice in allergic bronchopulmonary aspergillosis and the gross appearance of these may be mistaken for tumour. Carcinoid tumours are sometimes quite rounded and smooth, commonly sitting at the bifurcation of a more proximal bronchus. Their reputation for bleeding is an encouragement to the bronchoscopist to spray the suspect lesion with a bolus of 5 mL 1:20000 epinephrine (adrenaline) solution before taking a biopsy [94]. Endobronchial involvement by lymphoma [95,96] may sometimes consist of single or multiple nodules or mass lesions, some of which may protrude from bronchial orifices in polypoid fashion. Almost 50% of patients with AIDS who had cutaneous Kaposi's sarcoma (KS) were found to have endobronchial involvement at necropsy [97]. Endobronchial KS was found in 15% of 580 HIV-positive patients coming to bronchoscopy over a 10-year period [98], and may occur in the absence of mucocutaneous KS elsewhere [97,99]. It may be evident as reddish areas of discoloration in the mucosal wall, which may be multiple and not unlike submucosal haemorrhages, or as a raised violaceous lesion that may unusually cause bronchial obstruction. KS is a vascular tumour so that biopsy may produce haemorrhage; biopsy is often unnecessary if KS is evident elsewhere. Endobronchial metastases may be seen from many different primary cell types, breast and colonic carcinoma being particularly common. Others include genitourinary tract and thyroid tumours, malignant melanoma, sarcomas (including KS) and lymphoma [80,100,101].

Some tumours may declare themselves less obviously as bronchial narrowing that shelves down gradually like a funnel so that conventional biopsy forceps slide off the bronchial surface tangentially in annoying fashion. Such 'shelving down' appearances are sometimes due to extrinsic compression rather than intramural invasion, in which case biopsies may yield normal tissue. Earlier bronchoscopes were limited in that biopsy tools could be passed into some of the upper lobe segments only with difficulty and sometimes not at all. The friction characteristics and flexibility of more modern instruments are such that the forceps and brush tools may be advanced with the tip of the bronchoscope held in a greater degree of flexion so that the upper lobes are usually more readily sampled. The sampling tools should not be forced through the flexed end of the bronchoscope or damage to the instrument may

result, and sometimes it is necessary to protrude the biopsy tool just beyond the end of the bronchoscope before applying full flexion with the target area in view. Occasionally a tumour that is radiographically large and centrally situated is frustratingly accompanied by entirely normal endoscopic appearances, presumably arising at segmental level and surrounding rather than invading the proximal bronchial tree.

In cases of haemoptysis it is sometimes possible to see a little blood issuing from a bronchus that subtends a more distal tumour that is itself not endoscopically visible. When cricothyroid puncture is used, a small amount of blood may be spilt into the lower parts of the bronchial tree and this may be difficult to distinguish from more distal bleeding.

### **Procedures for sampling through the fiberoptic bronchoscope** (see Table 8.2, p. 151)

Cooperation between the histopathologist, the microbiologist and the clinician is extremely important. The pathologist needs to be aware of the sampling techniques used in order to be able to advise how best to process the specimens and the microbiologist should be aware of the clinical background, particularly when bronchoscopy is used to determine the nature of presumed opportunistic infection in an immunocompromised patient. Teamwork is essential in this situation if the procedure is to be of full value to the patient.

### **Endobronchial biopsy**

Clear endobronchial tumour is easy to biopsy but the bronchus that funnels down gradually presents more of a problem. Such narrowing may sometimes be more easily biopsied using a 'spear forceps', the sharp point of which may be used to impale the bronchial wall in order to provide an anchorage so that the jaws of the forceps are less likely to slip off the area of interest (Fig. 8.4). Other innovations are biopsy forceps with a 'swinging jaw' or 'rat tooth' design, both of which may prevent such slippage. Alternatively, a double-hinged curette may be used to scrape the surface of the lesion, the curettings obtained being submitted for cytology. Endobronchial biopsy material obtained by forceps under direct vision is carefully teased off the cup of the instrument and placed in 10% formalin fixative. Visible tumour may be covered by slough and attempts should be made to clear this first using the biopsy forceps in order to improve the yield. Similarly, attempts should be made to wash away blood clot following biopsy before taking the next sample, in order to avoid filling the forceps with thrombus. Three or four biopsies of a plainly seen tumour usually suffice [102,103], although one study reported that five biopsies were needed to achieve a greater than 90% probability of obtaining at least

one positive sample in cases of carcinoma [104]. Sometimes a tantalisingly large piece of tissue is obtained, in which case the operator may choose to leave the closed forceps just protruding beyond the end of the bronchoscope so that the whole instrument and intact biopsy can be removed as one, rather than fragmenting the biopsy by withdrawing it through the narrow biopsy channel.

Biopsy material is often friable and as an alternative to putting it directly into fixative it can be gently teased off the forceps, using a wooden cocktail stick or equivalent, into a Petri dish (or similar shallow receptacle) containing normal saline or Ringer's solution. Larger pieces that are most suitable for histology may then be carefully transferred to the formalin fixative in the tip of a syringe. Any tissue debris that remains in the saline may be fragmented into tiny pieces too small to be processed as tissue biopsies and may be decanted into a further container and submitted as a sample for cytology.

### **Transbronchial lung biopsy**

Transbronchial (sometimes referred to as 'bronchoscopic') lung biopsies are made beyond the limits of direct vision and may be conveniently carried out under fluoroscopic control using a C-arm (Fig. 8.5) or other suitable device, although some bronchoscopists have been content to work without any such assistance [105]. Where there is diffuse disease that is bilateral, the tip of a larger-channel bronchoscope may be wedged into a laterally placed segmental bronchus in either lower lobe, as these usually accept the forceps comfortably. At this point, 5 mL of 1:20000 epinephrine solution is injected into the chosen segmental orifice in the belief that this diminishes the likelihood of serious bleeding [106]. The largest possible toothed biopsy forceps (Fig. 8.6) are then passed through the same segmental opening, while the end of the bronchoscope remains wedged into that segment; the progress of the forceps is followed by fluoroscopy, the shaft of the bronchoscope nearest the patient being held by the assistant, with gentle inward pressure, so that the bronchoscopist is free to advance the forceps. If the forceps reach the extreme periphery of the lung, pleuritic pain may be felt and the forceps are withdrawn a few centimetres to reduce the chance of pneumothorax. If the forceps are arrested early on in their journey, another basal segment is tried instead, as too proximal a biopsy runs a small risk of damaging a larger blood vessel. When the forceps appear to be well situated towards the lung periphery, the patient is asked to 'take a deep breath in and hold it' and the assistant is given the instruction 'open'. The forceps can often be seen to open on the fluoroscopy screen, and they are then pushed gently forwards until resistance is felt, whereupon the patient is asked to 'let all your air out' and the assistant is given the instruction 'close' when expiration is seen to be complete. The forceps are then firmly

withdrawn. An elastic tug followed by a feeling of 'give' is sensed and lung tissue may be seen to be pulled and to recoil back into place on the screen. This is usually a sign that a satisfactory biopsy has been obtained. The biopsy material is then placed in fixative for histopathology or normal saline for microbiology.

Transbronchial lung biopsy depends for its success on the forceps having invaginated and torn away lung tissue as well as bronchial mucosa (Fig. 8.7). A pale fluffy-looking specimen that floats is likely to be a good one, although one that sinks need not mean failure. While the assistant is attending to the specimens, the bronchoscopist holds the end of the bronchoscope firmly wedged up against the segment just sampled so that any local bleeding is contained. The procedure is then repeated in the same segment so that the bronchoscope continues to tam-

Fig. 8.4 Spear fiberoptic bronchoscopic forceps.

ponade effectively. In diffuse disease, three adequate-looking samples are probably sufficient for histology [107], although some work has shown an increase in positive histological yield with up to six biopsies [103]. Milman and colleagues [108] found no significant increase in yield when taking more than four biopsies in 93 cases of diffuse non-malignant disease. By the time all the biopsies have been taken, vision has usually been obscured by local bleeding and it is wise to keep the instrument wedged in the segmental bronchus for at least 5 min in order to enable clot to form and to prevent bleeding once the instrument is removed. A small amount of local bleeding is to be expected, although there is a danger that this might become uncontrollable if proper precautions are not followed. The patient's chest may be finally screened for evidence of a pneumothorax. It is our practice to keep patients who have had transbronchial lung biopsies in hospital overnight, with a repeat chest radiograph the next morning to exclude pneumothorax as a result of a 'slow leak'. In practice, pneumothoraces are seldom a problem; when they do occur, they are usually shallow so that active treatment may not be required. There are certainly reported series in which transbronchial lung biopsy for diffuse lesions has been carried out without fluoroscopy and as a day-case procedure [105]. Transbronchial biopsy should not be carried out bilaterally at the same session because of the small but real risk of bilateral pneumothoraces.

The same technique may be used to biopsy mass lesions that are situated peripherally (i.e. beyond bronchoscopic vision), provided that they are of sufficient size to be seen fluoroscopically and that the forceps can be directed towards them. The resolution of some equipment is such that lesions on standard chest radiographs become

Fig. 8.5 Fluoroscopy table with C-arm and screening equipment.

Fig. 8.6 Crocodile fibreoptic bronchoscopic forceps.

frustratingly less clear on the fluoroscopy screen and they may become impossible to localize on the lateral projection. However, such biplanar screening can aid in positioning the forceps in relation to the lesion in the anteroposterior view and the lateral projection can at least confirm to the bronchoscopist that the forceps are directed anteriorly or posteriorly as he or she would wish. As usual, before exposing the patient to even a small risk, the bronchoscopist needs to consider how the result of the examination is likely to influence management. There is little purpose in attempting the procedure for suspected neoplasm if the lesion will still be resected even though the result of the biopsy is negative.

It is possible to carry out transbronchial lung biopsies on patients who are being ventilated mechanically [109]. The risks should be expected to be greater in an intensive care situation because of the increased likelihood of associated problems in critically ill patients. These include serious hypoxaemia, bleeding and pneumothorax (particularly with positive end-expiratory pressure), and fluoroscopy should be used in this situation.

Fig. 8.7 Transbronchial biopsy: mechanism whereby acinar tissue may be obtained (see text for description of method).

### Bronchial brushings

Various types of bronchial brush may be used to collect both cellular and microbiological material, using direct vision when collecting from proximal areas of suspicion or fluoroscopic screening when sampling more peripheral sites. Brushes are now disposable and are contained in a plastic sheath. When tumour is seen proximally, forceps biopsy should be used first in the author's opinion, as a brush stroke may cause enough local bleeding to obscure the lesion and made subsequent biopsies problematical. When bronchial brushings are to be submitted for cytology, the brush is smeared directly on to a microscope slide using a circular motion; the brush is rotated firmly on to a small area of the slide using a second slide, this manoeuvre being carried out for about 5 s in order to minimize drying artefacts, each slide being immediately fixed in 95% ethanol contained in a Coplin jar [110]. Alternatively, the brush may be agitated in a tube of normal saline or Ringer's solution, which is then promptly submitted for cytological studies or microbiological culture.

### Bronchial washings and bronchoalveolar lavage

The earliest applications of BAL were therapeutic, with the intention of removing inspissated bronchial secretions from patients with severe attacks of asthma. This practice failed to gain general acceptance but is used in modified form as 'whole lung lavage' under general anaesthesia in the treatment of alveolar proteinosis (see Chapter 51). Later the technique was modified for diagnostic and research purposes using smaller volumes of lavage fluid as a safe and effective method for sampling selected areas of peripheral lung [111].

### Clinical approach

The instillation of normal saline down the channel of the fibreoptic bronchoscope and the retrieval of some of it into a 'trap' (see Fig. 8.1) by suction is used in routine practice, being frequently combined with other sampling methods such as biopsy and brushing. When the volume of saline is small (e.g. 10–20 mL) and is sprayed into the vicinity of a visible lesion, this procedure may be described as *bronchial washing*; samples are usually submitted for cytological examination in the laboratory, where they may be passed through an 8- $\mu$ m Millipore filter or centrifuged in order to make smears or other cellular preparations so that a search may be made for neoplastic cells. At the end of the procedure the channel of the bronchoscope may be rinsed out into a container with 10–20 mL normal saline so that cellular debris lost from brushes or biopsy forceps may be similarly sampled.

In certain circumstances larger volumes of fluid may be instilled in order that more peripheral lung tissue can be

sampled. The usual clinical reasons for doing this are (i) to look for neoplastic cells in the case of a suspicious peripheral opacity that is beyond the visual range of the bronchoscope; (ii) to look for acid-fast bacilli where there is a suspicious-looking peripheral infiltrate and when it has not been possible to demonstrate these organisms in sputum (occasionally a cavitating lesion suggestive of tuberculosis turns out to be neoplastic, so that it is as well to collect some aliquots of fluid for cytology as well); and (iii) to search for opportunistic organisms such as *P. carinii* in cases where there is a more diffuse infiltrate in a patient who is immunocompromised (e.g. AIDS, after transplant, acute leukaemia, myeloma, etc.) [112,113]. When this organism is suspected, an upper lobe is often chosen as this may provide a greater yield.

In general there is little if any purpose in submitting such samples for 'routine' aerobic or anaerobic culture of the more usual pathogens that cause pneumonia or infective exacerbations of bronchitis, since these microbes frequently colonize the nose and oropharynx and may well be picked up by the passage of the instrument through these microbiologically fertile territories, the suction channel becoming contaminated by all manner of organisms *en route* so that subsequent cultures do not necessarily reflect intrathoracic disease. These organisms may be sought in the lungs only if special precautions have been taken to avoid such contamination, as may be achieved by the use of a 'protected brush' (such as that designed by Wimberley) or if a semi-quantitative calculation of the microbial load is made by techniques that record numbers of colony-forming units (cfu). Such methods are not yet widely used in routine clinical practice but do have applications particularly in cases of severe nosocomial pneumonia on intensive care units (see Chapter 13). As a generalization and where BAL is used,  $>10^5$  cfu has been taken as a threshold indicating probable pneumonia,  $<10^4$  cfu indicating probable absence of pneumonia [114].

The volume of fluid used to sample more peripheral lung, for the usual purposes outlined above, is commonly in the order of 60 mL (given as two 30-mL aliquots) and frequently gives a return on suction of about 10–15 mL. Much larger volumes have been used, mainly for research purposes, but such high volumes are of no benefit for clinical diagnostic purposes. When 60 mL or more is used the technique can fairly be described as 'bronchoalveolar' rather than 'bronchial' washing and by convention the term *bronchoalveolar lavage* is used. The technique in clinical practice requires the tip of the bronchoscope to be wedged into a segmental or subsegmental bronchus thought to subtend the area of interest and the given volume of fluid to be injected down the channel, immediately being retrieved with low-pressure suction. Less irritation and coughing may occur if the bronchus is first rinsed with a small volume of 2% lidocaine; initial concerns about its bacteriostatic properties do not seem to

have been borne out in practice as the concentration is low [115]. Further modifications to the technique are made when BAL is used for research into either the cellular constituents of lavage fluid or the nature of epithelial lining fluid and some of these are mentioned below.

Occasionally BAL fluid may yield unusual findings consistent with rare pathologies, such as clumps of amorphous lipoproteinaceous material that may be found in alveolar proteinosis [116] or large numbers of alveolar macrophages that are found to contain haemosiderin using Perl's stain for ferric iron, suggesting pulmonary haemosiderosis, although somewhat similar cellular appearances may occur when there has been pulmonary haemorrhage due to other causes [117].

It is clearly of crucial importance for the bronchoscopist to work closely with those colleagues in the microbiology, cytopathology and histopathology laboratories and it is helpful to have a 'lead person' in the laboratory who is willing and able to take responsibility for coordinating efforts across departmental divides, according to the nature of the particular clinical problem that has to be solved. It is the responsibility of the clinician to make sure that sufficient information is passed to the relevant laboratory personnel, otherwise all endoscopic efforts may be thwarted.

### Research aspects

Much work has been carried out over the years to investigate whether the use of larger volumes of BAL fluid than are used in routine clinical practice would help to characterize and also yield useful diagnostic and prognostic information about various forms of diffuse lung disease, such as cryptogenic fibrosing alveolitis, extrinsic allergic alveolitis and sarcoidosis [118–121]. Much of this work has centred around the determination of the main cellular constituents and their relative proportions in BAL fluid in normal subjects and comparison of these with the findings from the lungs of groups of patients with known pathology. The fluid lining the epithelial layer of the respiratory membrane has also been a subject of interest for some researchers [122]. Although much interesting data have been collected, these have unfortunately not had a major bearing on routine clinical decision-making; indeed a sceptic has unfairly suggested that this line of research is likely to be about as much use as trying to determine the workings of an elephant by studying its bath water.

When large-volume BAL is being undertaken for research purposes in the evaluation of diffuse lung disease, care must be taken to avoid trauma to the bronchial mucosa so that samples accurately reflect peripheral cell counts and are not contaminated by bleeding. There is at present no universally standardized method and thus results from one centre are not necessarily

ily strictly comparable with those from another, although attempts have been made to rectify this in both Europe and North America [123,124]. The choice of segmental bronchus is not critical provided that the abnormality under investigation is diffusely distributed; in this case it may be preferred to wedge the tip into the middle lobe or lingular bronchus since a greater volume of fluid may be retrieved from either of these sites. Others prefer to sample a laterally disposed basal segment, although the choice may be influenced by the radiographic disposition of shadowing when the radiograph is abnormal.

For research purposes, sterile, non-bacteriostatic, normal saline is used, either at room temperature or warmed to 37°C and buffered to a pH of 7.4 by the addition of a calculated volume of 8.4% sodium bicarbonate solution (0.55 mL to 1 L normal saline). Aliquots of 20–60 mL are injected down the suction channel and immediately reaspirated using low-pressure suction. A total of between 60 and 550 mL has been used, 120–180 mL being commonplace [118–121,125–128]. Larger volumes than 300 mL are unlikely to be necessary and these increase the chance of febrile episodes following the procedure [129]. With gentle suction a proportion of the volume used may be recovered after each instillation, the fluid being ideally aspirated into a container that reduces cellular adherence to its walls, such as a silicon-lined glass bottle or a polyethylene or polycarbonate vessel. The fluid then needs to be transported to the laboratory on ice with minimal delay.

Most attention has centred around differential cell counts, the total cell counts per unit volume having been found to be unhelpful. Thus relatively high percentages of lymphocytes have been found in BAL fluid in many patients with extrinsic allergic alveolitis (hypersensitivity pneumonitis). A similar finding has been recorded in a lower proportion of cases of sarcoidosis, whereas the differential counts in cryptogenic fibrosing alveolitis (idiopathic pulmonary fibrosis) and fibrosing alveolitis associated with systemic sclerosis or other connective tissue diseases tend to show an excess of neutrophils sometimes also with increased eosinophils [120,121,130,131]. Recent work also suggests that the cell populations in BAL fluid are not homogeneous in a given patient with cryptogenic fibrosing alveolitis and that they may vary according to the extent of the abnormalities on HRCT in the lavaged lobe [132].

BAL had been proposed as one of a number of methods for determining the 'activity' of sarcoidosis (see Chapter 39) in order to try to separate those cases that if left untreated develop fibrosis and permanent impairment from those which resolve spontaneously. It has been claimed that a T-lymphocyte count of greater than 28% (especially if combined with a positive gallium scan) is an indication of an active alveolar inflammatory process or 'high-intensity alveolitis', so that fibrosis can be expected, whereas with lower counts the converse is more likely

[133]. Unfortunately some patients with sarcoidosis who have hilar lymphadenopathy only and clear lung fields on the radiograph may fulfil the lavage criteria of 'high-intensity alveolitis' and yet be followed to apparently complete resolution, so that this lavage parameter cannot be relied upon as a sound base for therapeutic decisions regarding corticosteroid therapy [121]. This is further borne out by the observation that patients with sarcoidosis who have evidence of fibrosis on lung function testing and who have normal lymphocyte counts in lavaged fluid may yet respond to corticosteroid treatment.

In patients with cryptogenic fibrosing alveolitis it has been similarly suggested that a relative increase in the BAL lymphocyte count in lavaged fluid may be an indication of steroid responsiveness, possibly carrying a better prognosis [134]. The clinical usefulness of this observation is again questionable as some patients with cryptogenic fibrosing alveolitis with relatively high neutrophil counts also respond to steroids [121]. A better clinical response to steroids or cyclophosphamide has also been correlated with a relatively low eosinophil count on BAL [121].

Further research into the significance of lavage fluid cell counts has extended to counts of T-lymphocyte subsets but whether this will prove clinically helpful has yet to be shown [135].

### Per-bronchoscopic needle aspiration

The development of various needle devices that can be passed down the channel of the fiberoptic bronchoscope has provided another method for obtaining samples of the cellular content of suspected areas of neoplastic involvement [136]. A number of such needles have been designed [137]. One version consists of a hollow rigid 19-gauge needle attached to the distal end of a flexible wire, this sampling needle containing a solid 22-gauge needle 'core'; the whole arrangement is housed in a plastic catheter, the proximal end of which has a side-port, allowing suction to be applied, along with a slide mechanism that facilitates manual advancement of the needle beyond the end of the catheter [137,138]. This allows a bronchoscopist who has mastered the technique to advance the larger hollow cutting needle over the smaller solid needle in order to enter a centrally placed extrabronchial lesion, such as an enlarged subcarinal node. The sample is retrieved by applying suction to the side-port and the central solid needle prevents the cutting needle from becoming obstructed by tissue from the tracheobronchial wall itself. The contents of the cutting needle may then be expelled, either by positive pressure from a syringe on the side-port or by advancing the solid central needle, in order to obtain specimens for histology or cytology according to their size. The yield from cytological samples may be better if they are placed on a microscope slide and fixed immediately in alcohol [137].

There are three main applications of per-bronchoscopic

needle aspiration. The first involves the sampling of central (carinal, paratracheal and hilar) lymph nodes or other mediastinal lesions by puncturing the tracheo-bronchial wall in the manner described above [137,138]. This technique has therefore been used by *aficionados* in the staging of lung cancer in order to avoid the need for mediastinoscopy [139,140], prior CT of the mediastinum indicating the position of the enlarged nodes to be sampled [140,141]. Caution must be exercised before discharging a patient with a positive mediastinal needle sample as being surgically inoperable since false-positive results, although uncommon, may occur due to the potential for contamination of the needle by neoplastic cells from various areas, including those that have been carried up in bronchial secretions from more distal parts of the tracheobronchial tree [142,143].

The second use is to sample peripheral 'mass shadows' using the same type of fluoroscopic control as that described above for transbronchial lung biopsy [144]. Once the lesion has been 'found' a smaller-gauge flexible needle is advanced and retracted while suction is applied. Such flexible needles have the advantage of allowing access to lesions that are inaccessible to a rigid needle, such as those situated in the apical segments of the upper lobes. It has been reported that yield may be increased if needle aspiration is combined with other sampling methods such as conventional transbronchial biopsy with forceps [145]. There is some evidence to suggest that transbronchial needle biopsy may be better than transbronchial biopsy and brushing at retrieving neoplastic cells from nodular smooth-walled peripheral lesions compared with irregular-walled more infiltrative lesions [146].

The third use is to sample proximal endobronchial lesions that have to be approached by the bronchoscope at a narrow angle so that the operator may find them awkward to biopsy should conventional forceps fail to find a proper purchase and slip off. Such mural tumours are less easily biopsied and needle aspiration may be effective in this situation [102]. The needle may also offer a potential advantage over forceps when a tumour is apparently covered by slough but this has yet to be demonstrated.

Apart from the potential problem of false positivity, other difficulties may arise with needle aspiration.

- 1 The fear of false negatives leads to a reluctance to diagnose benign conditions, so that a further more invasive procedure is likely to follow anyway.
  - 2 There may be difficulties distinguishing different histologies (e.g. non-small-cell vs. small-cell cancer), especially on cytological samples.
  - 3 There is a potential risk of haemorrhage, either into the bronchial tree or mediastinum.
  - 4 Incautious use of the biopsy tool may damage the bronchoscope.
- Transbronchial needle aspiration biopsy is probably the least widely used of the various fiberoptic bronchoscopic

techniques; about 12% of 871 North American respiratory physicians who responded to a questionnaire claimed to use it routinely in 1991 [147]. This relatively poor uptake probably reflects not only concerns about the problems just listed but also the difficulties in learning a technique that inevitably increases the complexity of already busy lists. It has been estimated that a training experience of about 50 procedures is required to achieve acceptable results [148].

## Diagnostic yield of fiberoptic bronchoscopy

### Lung cancer

#### Visible endobronchial tumour

The diagnostic yield from biopsy of bronchoscopically visible tumours that occupy the lumen of the bronchus is, in the best analyses, over 90% [103,149–151]. The number of biopsies taken to achieve this should be three or four [102,103] and it is possible that increasing the number of biopsies might correct any tendency towards a lower yield in a relatively inexperienced operator, although this has not been shown. The yield for bronchial brushings/washings submitted for cytology in the same situation may be almost as high as biopsy given expert cytopathological support [149,152], which is not available in all institutions. There is good evidence that the positive yield is increased if specimens are submitted for both cytology and histology [153–155]. A British study in a group of 125 endoscopically visible tumours found positive biopsy results in 76%, positive bronchial washings in 50% and positive brushings in 52%. Biopsy and brushings together gave a yield of 97%, biopsy and washings a yield of 95%, but washing and brushing together a yield of only 74% [155]. There was usually more than one positive in each case, so that biopsy gave the only positive in 22%, brushing in 5% and washing in 2% [155]; the clear message is to combine the different techniques. False positives may occur with cytology but are rare [152].

Small biopsy samples such as those obtained by fiberoptic bronchoscopic biopsy result in appreciable histological inaccuracies if attempts are made to type according to the World Health Organization's classification of lung cancer and a simplified classification comprising either 'small cell carcinoma' or 'non-small-cell carcinoma, not further specified' has been suggested in its place for this type of small biopsy [156].

#### Visible intramural tumour

The yield from the technically more uncertain biopsy of bronchoscopically visible tumours that are intramural rather than endobronchial is predictably less good. A positive yield of 55% in 31 such cases has been reported [102]. However, this was increased to 87% when the biopsy was

supported by transbronchial needle aspiration and 97% when bronchial washings and brushings were submitted for cytology as well [102].

### *Peripheral tumour*

The diagnostic yield in the case of peripheral tumours beyond bronchoscopic vision is bound to be lower and more variable. Factors that influence yield include the skill and experience of the bronchoscopist, the time available for the procedure, the availability of supporting fluoroscopic facilities and their competent operation, the size of the lesion and whether it is a primary or secondary deposit. The yield has also been noted to be lower if the lesion has a sharp rather than an irregular border [157].

Previous bronchoscopic experience has been shown to influence the rate of positivity following biopsy of visible endobronchial tumour [104] and it can therefore be inferred that the same factor is likely to operate at least as strongly in the technically more difficult biopsy of peripheral lesions.

The absence of fluoroscopy turns attempts to biopsy a peripheral lesion into a much more haphazard affair as even the most experienced operator can do no more than choose what appears to be the correct bronchopulmonary segment and hope, having no idea whether the end of the forceps has reached the lesion or not. An arrangement by which screening can be carried out in two planes is necessary so that the patient is moved in relation to the X-ray beam by means of a rotating C-arm or some other device. One early study demonstrated an increased diagnostic yield from 30% without screening to 80% when screening was available [158]. The results of two large studies, one of which used fluoroscopy [159] and the other not [155], showed that biopsy achieved a positive result in 61% with fluoroscopy vs. 37% without, bronchial lavage a positive result in 52% with vs. 38% without and bronchial brushing a positive result in 52% with vs. 29% without. When all three techniques were used the success rate was 86% with fluoroscopy compared with 57% without [155,159].

Unsurprisingly, the size of the lesion influences yield: the positive yield is lowest with lesions less than 2 cm in diameter, usually 35% or less [160–162], small lesions being easily lost as a result of relatively poor fluoroscopic resolution. They are also likely to be subtended by fewer bronchi, thereby reducing the chance of the forceps, brush, curette or needle reaching them, for once these instruments have been placed in a bronchial segment or subsegment the bronchoscopist loses control over the route that they take. Combined sampling techniques and the use of fluoroscopy enhances the yield, one series reporting a higher overall positive yield for lesions of 2 cm or less of 54% increasing to 87% for those over 5 cm, using an approach that combined brushing, transbronchial biopsy and transbronchial needle aspiration [157].

The overall yields for biopsy and brushing of peripheral

lesions has been reported to vary widely between 30 and 90% [163]; for biopsy alone in such lesions, one study reported positive results in 46%, the yield increasing to 60% with brushing as well [164]. A further study reported a positive yield from biopsy alone in 75% of cases [103]. Positive yield was likely to be increased if six or more biopsies were taken [103]. The use of bronchial washings and brushings may augment the yield from transbronchial lung biopsy alone [163], as may per-bronchoscopic needle aspiration. Using a technique of needle aspiration, positive results in over 70% of tumours 2 cm or more in diameter have been reported compared with a 33% yield for smaller lesions [163].

The yield is lower for peripheral metastatic tumours that are beyond bronchoscopic vision, positive results for transbronchial lung biopsy being reported in 50% of cases of metastatic cancer compared with almost 70% for peripheral primary lung cancer [149]. Similar yields have been found by other workers [165]. On the other hand, lymphangitis carcinomatosa, being diffuse, is usually readily diagnosable by transbronchial lung biopsy assuming that the patient is fit enough to undergo the procedure [166].

## **Diffuse non-neoplastic lung disease**

### *Sarcoidosis*

Transbronchial lung biopsy is a very useful technique when it is considered important to obtain lung tissue to confirm a diagnosis of sarcoidosis (see Chapter 39). The success rate of this method in all stages of sarcoidosis has been reported to lie between 60 and 90%, the yield being greater when an infiltrate is visible on the radiograph [167–169]. One such study found that four transbronchial lung biopsies achieved a yield of 90% [170]. Endobronchial biopsies may also give the diagnosis in sarcoidosis [171] and these should be taken if mucosal lesions are seen. It has been claimed that such changes may be seen in up to 10% of patients with all stages of sarcoidosis [80]. Endobronchial changes consistent with sarcoidosis may be found histologically in 20–70% of cases [87] but random biopsy of normal-looking mucosa will probably not increase the diagnostic yield from transbronchial biopsy significantly.

### *Other diffuse non-infectious disease*

With the possible exceptions of alveolar proteinosis, in which alveoli contain a typical strongly eosinophilic and PAS-positive granular exudate, and idiopathic pulmonary haemosiderosis, in which alveoli contain numerous haemosiderin-laden macrophages, diffuse lung diseases of a non-infectious nature, other than sarcoidosis [171] and lymphangitis carcinomatosa [166], are much less likely to be reliably made on small pieces of tissue such as those

provided by transbronchial lung biopsy. Frequently the histopathological reports on such samples describe non-specific changes that could represent the end-stage of innumerable inflammatory processes or at best may report changes that are 'consistent with' whatever diagnosis the clinician was considering rather than being 'diagnostic' of a given pathology.

Wall, Gaensler and colleagues [15] carried out a prospective trial in such cases to ascertain the reliability of transbronchial lung biopsy in comparison with open lung biopsy; 53 patients underwent transbronchial lung biopsy and the procedure was diagnostic in only 20 (38%); over half these patients had sarcoidosis. The remaining 33 patients in whom the tissue diagnosis following transbronchial lung biopsy was uncertain were submitted to open lung biopsy, which achieved a specific diagnosis in 92%. These diagnoses bore little relationship to those put forward after transbronchial biopsy. The conclusion from this was that transbronchial diagnoses of cryptogenic fibrosing alveolitis (interstitial pneumonitis, interstitial pulmonary fibrosis), chronic inflammation, 'non-specific reactions' and fibrosis were unreliable and often misleading [15]. Other studies in which a comparison has been made between transbronchial and open lung biopsy have shown good agreement in a higher proportion of patients (62%) but have been much smaller, involving only 16 patients [172,173].

Although there is a lack of consensus concerning the best method by which lung tissue should be sampled to confirm the diagnosis and assess the degree of activity in cryptogenic fibrosing alveolitis, the argument is strong for carrying out open (or thoracoscopic) lung biopsy when it is considered necessary to obtain tissue [174]. In practice, once the balance of the risks as against the potential benefits of invasive investigation have been discussed with the patient, treatment is often started without histology when the diagnosis of cryptogenic fibrosing alveolitis seems highly probable on the basis of the whole clinical picture, including the result of HRCT.

Diffuse lung disease in patients with HIV is usually indicative of secondary infection but may occasionally be due to lymphocytic or non-specific pneumonitis, which can only be diagnosed by transbronchial or some other form of lung biopsy [175].

## **Pulmonary infection**

### ***Mycobacterial infection***

When active tuberculosis is suspected, fiberoptic bronchoscopy may be carried out in those patients who are unable to raise an adequate sample or in whom sputum is negative on direct staining for acid-fast bacilli [28,29,176–180]. Mycobacteria may be more easily detected if auramine staining with fluorescence rather than Ziehl–Nielsen staining is used. Material that can be examined

includes bronchial lavage fluid, endobronchial biopsies (where lesions are seen), bronchial brushings, transbronchial lung biopsies and postbronchoscopy sputum. The immediate positive yield in patients shown subsequently to have active tuberculosis is about 50% by acid-fast staining of transbronchial lung biopsies or other material [177,181]. One study found that of 56 positive bronchial brushings, 63% were immediately positive on direct smears and 37% only on culture [28]. Other studies have reported that tuberculosis is diagnosed by culture of fiberoptic bronchoscopy material, such as bronchial brushings (brush agitated in normal saline) or transbronchial lung biopsy, in about 30–50% of patients [177,178]. Miliary tuberculosis that is negative on sputum smear can also be diagnosed bronchoscopically, the highest yield coming from transbronchial lung biopsy followed by bronchial brushing and bronchial lavage [182]. There is some evidence to suggest that sputum induction using nebulized hypertonic saline may provide a diagnostic yield as good as bronchoscopy, the clear implication being that this simpler and less invasive test should be tried first [183].

The diagnosis of tuberculosis may sometimes be made by biopsy of endobronchial lesions found in patients with tuberculous hilar or mediastinal lymphadenopathy in the absence of lung parenchymal abnormalities [184]. The diagnosis can also be made by transbronchial or transcarinal needle biopsy of the enlarged lymph nodes themselves [184]. Endobronchial abnormalities are also not uncommon in patients with active lung parenchymal tuberculosis, being found in one-third of cases in one series [185]. Bronchoscopy was found to add little to the diagnostic yield in a hospitalized group studied in Dar es Salaam, a resource-poor area where tuberculosis is endemic, this disease being the most common cause of pulmonary infection (irrespective of HIV serological status), accounting for over 75% of disease in both HIV-positive and HIV-negative groups whereas *P. carinii* pneumonia was found in only 1% of the HIV-positive group [186].

In Taiwan, despite the high prevalence of tuberculosis, cancer was still found to be the commonest cause of a solitary pulmonary nodule, although tuberculosis accounted for 24% of such cases. Fluoroscopically guided brushing and transbronchial lung biopsy yielded the diagnosis of this infection in 55% of those in whom it could not be made by sputum smears [162].

*M. tuberculosis*, *M. avium-intracellulare* and other 'atypical' mycobacteria may also be isolated from immunocompromised patients [98,187,188]. A survey of patients with AIDS in England and Wales found that 4.6% had tuberculosis [189], and non-tuberculous mycobacteria may be detected with increasing frequency as AIDS progresses [190,191]. Visible endobronchial changes have been found in about 25% of HIV-infected patients with pulmonary tuberculosis [93]. Combined transbronchial biopsy and BAL has been claimed to have a sensitivity of 90% in diag-

nosing *M. avium-intracellulare* infection in patients with AIDS [126]. The finding of this organism in such circumstances is generally considered to be of pathological significance [192].

### Fungal infections

*P. carinii* pneumonia (see Chapter 52) may occur in many conditions in which the patient's cellular immunity is compromised, such as leukaemia, lymphoma, during the use of cytotoxic and other immunosuppressant agents for both neoplastic and non-neoplastic disease, and following organ transplantation [23]. This fungal organism is also recognized as the most important opportunist pathogen causing pneumonia in AIDS, accounting for 65–85% of cases in developed countries [112,192,193]. Fiberoptic bronchoscopy has been shown to be a highly effective means of establishing the diagnosis of *P. carinii* pneumonia in such patients. In a series of 171 patients with AIDS, from whom 127 isolates of *P. carinii* were obtained, it was reported that the sensitivity of BAL was 89% compared with 97% for transbronchial lung biopsy [126]. Where both procedures were used, a sensitivity of 100% was achieved. The authors stressed the importance of both adequate lavage and experienced and competent laboratory personnel. Fiberoptic bronchoscopy has also been found to produce a high diagnostic yield in *P. carinii* pneumonia by other workers [112,127,194]. There has been a trend to rely increasingly on the less invasive BAL, with a decline in the transbronchial lung biopsy rate, as it has become clear that BAL has a high diagnostic accuracy and a low rate of false negatives for *P. carinii* in experienced hands [98] as well as lower morbidity [194]. The yield may be higher if the upper lobes are lavaged [194]. The sediment obtained from BAL fluid is now usually examined using a direct immunofluorescent test, employing monoclonal antibodies against *P. carinii*, which demonstrates brightly stained cysts. Transbronchial lung biopsies may also be subjected to various conventional silver stains, such as Grocott–Gomori's methenamine silver stain for cysts and the modified Wright–Giemsa (or Diff Quik) stain for trophozoites, which may show them as minute dots in the alveolar spaces. The commencement of treatment for *P. carinii* pneumonia before bronchoscopy does not appear to prevent subsequent detection of the organism, as the cysts persist for days or sometimes even weeks after treatment, but prophylactic aerosolized pentamidine may reduce the yield from BAL so that the addition of transbronchial lung biopsies may be appropriate in this circumstance [194].

The recovery of fungi other than *P. carinii* from BAL fluid can cause difficulties in immunodeficient patients with apparent pneumonia, as it may not be clear whether such isolates are colonists or the genuine invasive cause of fungal pneumonia. *Aspergillus fumigatus* in particular is ubiquitous and is a common lung saprophyte. Purists

insist on histological evidence of lung parenchymal invasion by transbronchial biopsies coupled with a positive culture result, although clinicians often treat on the basis of strong suspicion, such as the finding of large numbers of fungi in the BAL fluid. Transbronchial lung biopsies are not always possible in such cases, as these patients not infrequently have thrombocytopenia as well as neutropenia. Various organisms other than *Aspergillus* species may be implicated, including *Cryptococcus neoformans*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Candida albicans* and the Mucoraceae causing pulmonary mucormycosis (see Chapter 21). A test for cryptococcal antigen may be run on BAL fluid and is useful in patients with HIV infection, who are particularly susceptible to infection by this organism [195].

### Viral infections

CMV is the commonest cause of viral pneumonia in patients who are immunosuppressed by drugs and in those with HIV infection. This virus has a tendency to cause infection in a recipient 6–8 weeks after transplantation of solid organs and, more particularly, bone marrow [194]. It has been suggested that such infection may be a factor in causing obliterative bronchiolitis in lung transplant recipients, although this remains controversial [18]. CMV was isolated from 43% of initial bronchoscopies in 171 patients with AIDS [126]. This organism may sometimes be a colonist rather than an invader and its clinical significance as a cause of pneumonia has been frequently questioned [98,196,197]. CMV may be cultured from bronchoalveolar washings and from transbronchial lung biopsies, although this may take several weeks and thus other methods have to be used. Evidence of infection, but not necessarily disease, may be provided by the typical 'owl's-eye' inclusion bodies on transbronchial lung biopsies. Positive immunofluorescent testing (by detection of early antigen fluorescent foci) of infected cells in BAL fluid or transbronchial lung biopsies may help to put the diagnosis on a firmer footing within a short time. CMV has also been detected in such specimens by the polymerase chain reaction technique.

Bronchoscopy is not ordinarily used to diagnose the microbial cause of pneumonia in immunocompetent patients [198] other than in those situations mentioned in the preceding paragraphs, with the exception of severe ventilator-associated pneumonia on intensive care units, in which case a protected brush is sometimes used [199,200] or semi-quantitative bacterial counts may be applied using numbers of colony-forming units as a diagnostic yardstick [114] (see p. 161 and Chapter 13).

### Complications of fiberoptic bronchoscopy and transbronchial lung biopsy

The general safety of fiberoptic bronchoscopy may lull the

operator into a false sense of security, for sudden complications do occur and rare fatalities are recorded in both the literature and physicians' memories. Such catastrophes can be guarded against by correct application of technique and by bronchoscopists and their staff being in a state of preparedness, so that when difficulties do arise they are dealt with swiftly and decisively.

### Mortality

Retrospective postal surveys rely on the accurate recall of events that the respondent might prefer to forget and therefore underestimate the total number of deaths. One such survey reported a mortality rate of 0.01% from 24 501 bronchoscopies, another found 0.02% from 48 000 investigations, and a third 0.04% from 39 564 procedures [52,201,202]. Prospective studies from single centres have naturally been much smaller and have recorded higher mortalities of 0.1% of 908 bronchoscopies and 0.5% of 205 bronchoscopies, the authors of the last work implying that the high mortality rate might have been related to the fact that the procedures were carried out by medical staff in training [150,203].

Of the multicentre series, the two deaths reported by Credle and colleagues [201] both occurred during the procedure in seriously ill and intubated patients. The 12 deaths in the series by Suratt and colleagues [202] were accounted for by two reactions to the topical anaesthetic (tetracaine) prior to the procedure, two massive bleeds from previously slowly bleeding tumours and two myocardial infarctions; of the remainder, chronic respiratory insufficiency, severe pneumonia, carcinoma and heart disease were coexisting factors. The most common cause of mortality associated with fiberoptic bronchoscopy in the series by Simpson *et al.* [52] was cardiovascular (myocardial infarction or left ventricular failure), accounting for 5 of 13 deaths; of the remainder two were attributed to haemorrhage, two to 'bronchospasm', two to 'advanced neoplasia', one to aspiration pneumonia and the other to a general anaesthetic. This study also found a higher incidence of deaths in teaching hospitals but attributed this to the observation that patients in teaching hospitals were 1.64 times more likely to undergo transbronchial biopsy during the procedure [150].

A retrospective postal survey of 2628 transbronchial lung biopsies found a mortality rate of 0.5% for this procedure, the most common cause being haemorrhage which accounted for nine of a total of 13 deaths [204]. Of these deaths eight occurred in patients who either had diseases or were taking drugs known to affect coagulation; of the remaining deaths two were associated with refractory hypotension, one with severe hypoxaemia and others occurred as a result of tension pneumothorax [204]. The estimated 3387 transbronchial lung biopsies in Simpson *et al.*'s series were associated with a mortality rate of 0.12% for this procedure; three of these four deaths were due to

haemorrhage (two in patients with leukaemia), the remaining death being attributed to pneumothorax in a patient with advanced neoplastic disease [52].

### Morbidity

Retrospective studies of fiberoptic bronchoscopy have found a major complication rate of 0.08–0.3%, 'major complication' having been defined as one considered to endanger life or requiring urgent therapeutic intervention [52,201,202]. Prospective studies report higher major complication rates of 1.7–5% [150,203]. Major complications have been found to occur 20 times more frequently when transbronchial lung biopsy is used rather than standard fiberoptic bronchoscopy, the figures being 0.12 and 2.7% respectively [52]. The two most important complications of transbronchial lung biopsy are pneumothorax and haemorrhage.

### Pneumothorax

Two series found that pneumothorax was the most common serious transbronchial complication, occurring in 5.5% and 2.9% of 2628 and 3387 procedures respectively [52,204]. The use of radiological screening reduced the incidence of this complication by almost 40% from 2.9 to 1.8% in one series [52]. The incidence of pneumothorax was 15% in one small series in which fluoroscopy was not used [205]. Small air leaks need no intervention other than observation, although intercostal tube drainage may be anticipated in 40–65% of cases and delayed pneumothorax may occur some hours later, presumably due to slow leaks [52,108,206,207]. Fatalities have occurred (see above). Pneumothorax may be more common when transbronchial biopsy has been carried out for diffuse rather than localized disease but need not be related to the number of biopsies taken [108]. HIV-infected patients with *Pneumocystis* pneumonia already have an increased incidence of secondary spontaneous pneumothorax [208] and these patients also appear to run a greater risk of iatrogenic pleural leaks; in one series 9% of 100 HIV-infected patients undergoing transbronchial lung biopsy developed pneumothorax and over half of them required tube drainage [126].

### Haemorrhage

This is the second most common serious complication of transbronchial biopsy and the most feared. The definition of a 'serious' pulmonary haemorrhage is problematical and subjective. One study recorded bleeding estimated to exceed 50 mL in 1.3% of 2628 cases; another reported that 0.5% of 3387 transbronchial biopsies were accompanied by 'major' bleeding [52,204]. Series in which transbronchial lung biopsy has been carried out in immunocompromised patients suggest a higher incidence of

significant endobronchial bleeding of about 5% [209]. A series that reported the complication rate of transbronchial lung biopsy in 24 thrombocytopenic patients (platelet range  $7\text{--}60 \times 10^9/\text{L}$ , mean  $30 \times 10^9/\text{L}$ ) reported serious endobronchial bleeding with a minimum estimated blood loss of 80 mL in four patients (17%), one of whom (4%) died of haemorrhage. Most of these patients had leukaemia and 67% died later as a result of the underlying condition [209]. The minimal platelet count necessary prior to performing transbronchial lung biopsy or bronchial brushing in peripheral lung is unclear but the requirement of a count greater than  $50 \times 10^9/\text{L}$  is usual [209]. There needs to be a compelling reason for the investigation at platelet counts below this level. There is little evidence to demonstrate the efficacy of measures to prevent alarming intrabronchial haemorrhage following transbronchial biopsy but the following are recommended.

1 Use of a routine 'clotting screen' before biopsy, e.g. platelet count, prothrombin time, activated partial thromboplastin time (and a bleeding time if a history suspicious of a haemorrhagic tendency is obtained). Platelet function may be impaired in a qualitative rather than a quantitative sense by aspirin and other drugs, plasma cell dyscrasias, other myeloproliferative disorders and systemic lupus erythematosus [209]. When a coagulopathy is suspected or confirmed, it seems prudent to carry out these screens within 12 h of bronchoscopy. Haematological advice should be taken about the finding of a systemic coagulopathy, which should be corrected with appropriate replacement, such as fresh frozen plasma, vitamin K, etc., before biopsy is undertaken.

2 Correction of thrombocytopenia (6–12 fresh platelet packs for a count of less than  $50 \times 10^9/\text{L}$ ).

3 Avoidance of biopsy or brushing in patients with uraemia (see pp. 169–170), which also impairs platelet function.

4 Local application of 5 mL of 1:20 000 epinephrine solution before biopsy.

5 Use of the 'wedge technique', where the bronchoscope tip tamponades a bleeding segment [210,211] (see p. 159).

6 Availability of a balloon catheter of suitable size for passage down the suction channel (e.g. Fogarty no. 4 or purpose-designed bronchoscopic balloon catheter) in order to tamponade a bleeding bronchus [212,213]. If such a catheter is not available in the presence of massive haemorrhage, asphyxiation may be prevented by isolating the bleeding lung with a single-lumen endotracheal tube passed into the other main bronchus. Such 'blind' intubation until resistance is felt usually places the tube in the right main bronchus, allowing ventilation of the middle and lower lobes. It may also be possible to selectively intubate the left main bronchus when the right side is bleeding, by passing the tube with the patient's head turned to

the right and with appropriate positioning of the bevel of the tube [214]. It is also usual to place patients on their side, with the bleeding lung most dependent in order to protect the other lung.

7 Availability of a competent rigid bronchoscopist with appropriate instrumentation for suction and per-bronchoscopic tamponade is also an advantage, although such a person (now usually a thoracic surgeon) will not be readily available in many smaller units [52,215].

Clearly the risk of haemorrhage is much higher in some patients than others, and aggressive bronchoscopists performing a biopsy in pursuit of opportunistic organisms or other diagnoses in perilously ill, immunosuppressed patients with uraemia, leukaemia or other blood dyscrasias are more likely to encounter serious haemorrhage than those whose practice is more mundane [204,210]. In such cases bronchial lavage without biopsy often gives a high yield with minimal risk. Severe haemorrhage may also occur as a result of endobronchial biopsy of visible tumour, although this is unusual. Vascular tumours such as KS have a propensity to bleed when interfered with and injudicious transbronchial needle biopsies by the less-experienced operator in the vicinity of centrally placed major vessels may court disaster.

### *Complications of sedation and topical anaesthesia*

One survey found that about half of all life-threatening complications were related to either premedication or topical anaesthesia [201]. Topical anaesthetics may cause epileptic seizures and cardiac dysrhythmias as already described [72,201]. Premedication also usually employs sedative drugs that may result in hypoventilation, as described in an earlier section. In another large survey, 7 of 10 episodes of life-threatening hypoventilation followed the use of intravenous sedatives [52]. It is conventional to guard against hypoventilation by reducing the dose of a sedative or omitting it altogether in patients who may be at risk, such as the elderly or those with significant pre-existing impairment of lung function. Where there is doubt about the advisability of a sedative, it is best omitted and patients often tolerate the procedure without one [216].

A maximum dose of 300–400 mg of lidocaine has been recommended for topical anaesthesia [217,218] and despite the fact that this dose is sometimes exceeded in practice [52], serious reactions occurred in only two patients in one series of 39 564 bronchoscopies [52]. Nevertheless, caution is advisable as both fatalities and serious complications have been described, and blood levels of 30–50% of an intravenous dose of local anaesthetic may follow the application of the same dose to a mucous membrane [201,202,219]. There is evidence to suggest that the topical application of lidocaine to the airways may also result in some airflow limitation [220].

Laryngospasm may occur, possibly as a result of inadequate anaesthetization of the larynx, although this is not clear. It was the most frequently reported complication in one series and may cause the bronchoscopy to be hurriedly abandoned [201].

#### *Other respiratory and cardiovascular complications*

Although the safety of fibreoptic bronchoscopy in mild asthma has been stressed [221,222], serious reactions in asthmatic patients are a well-recognized complication of the procedure [223,224]. The series of Dreisin *et al.* [150] recorded severe bronchospasm in three of four asthmatic subjects, with death in one. In the series of Credle and colleagues [201], six asthmatic patients had similar reactions and two required intubation. A UK postal survey recorded three major complications and two deaths ascribed to bronchospasm [52]. Various untested recommendations have been made in order to avoid serious bronchial reactions in asthmatic patients [118]. Such precautions include the administration of an intravenous bolus of 100 mg hydrocortisone before the procedure, intramuscular atropine 0.6 mg as premedication, 2.5–5.0 mg nebulized salbutamol before bronchoscopy, the limitation of lavage fluid to 200–300 mL with its heating to body temperature, and the provision of oxygen while monitoring pulse oximetry, a practice that is now routine.

Cardiovascular complications range from minor vasovagal episodes to serious cardiac dysrhythmias, myocardial infarction and pulmonary oedema, of which the last two were the most common causes of death in one postal survey [52]; 27 life-threatening cardiovascular complications occurred in 48 000 bronchoscopies surveyed in the USA [202]. Although published data to support the efficacy of preventive measures in these circumstances are sparse, sensible precautions involve the ready availability of equipment for cardiopulmonary resuscitation and the avoidance of hypoxaemia by means of pulse oximetry and appropriate provision of supplemental oxygen. Bronchoscopy should be avoided in patients with unstable cardiovascular symptoms. It may be carried out in patients who have had a myocardial infarction within the previous month provided that a strong indication exists [225,226].

Hypoxaemia has long been recognized as a potential complication of fibreoptic bronchoscopy, one study having found an average fall in  $P_{aO_2}$  of 2.7 kPa (20 mmHg) in 18 subjects [227–229]. A correlation between hypoxaemia and cardiac events has also been found, transient atrial and ventricular ectopic activity being most evident with maximum desaturation when the bronchoscope was in the region of the larynx [230]. Although such problems are rarely of clinical significance, the provision of supplemental oxygen and pulse oximetry as a routine is sensible [231]. Cardiac monitoring is also carried out routinely in some centres but is by no means universal.

**Table 8.3** Relative contraindications to fibreoptic bronchoscopy and biopsy under topical anaesthesia (see text).

Uncooperative patient
Uncorrectable hypoxaemia/hypercapnia
Unstable myocardium
Uncorrectable bleeding tendency
Tracheal stenosis
Poorly controlled asthma

#### *Miscellaneous complications*

Episodes of fever following fibreoptic bronchoscopy are described but supportive evidence of infection is unusual and bacteraemia rare [232]. The older literature suggests that bronchoscopic instrumentation in the vicinity of a large lung abscess may be hazardous as it carries the potential risk of rupture of the abscess with subsequent flooding of the bronchial tree by a sufficient volume of pus to overwhelm the suction channel.

#### **Contraindications to fibreoptic bronchoscopy and biopsy**

Contraindications to fibreoptic bronchoscopy are listed in Table 8.3; some have already been alluded to in the preceding section. Few of them are absolute. As fibreoptic bronchoscopy is normally carried out with only topical anaesthesia and sedation, a reasonable level of patient cooperation is required, otherwise the procedure is a waste of time and the instrument at risk of damage. Severe respiratory impairment present before bronchoscopy is likely to be worsened and it is our practice to carry out arterial blood gas analysis in patients whose  $FEV_1$  is less than 1 L or who have diffuse lung disease with tachypnoea at rest or on minimal exertion. If the  $P_{aO_2}$  is less than 9.0 kPa (about 70 mmHg) and if it cannot be safely corrected to this figure by supplemental oxygen, then this may be regarded as a contraindication to bronchoscopy, as is a raised  $P_{aCO_2}$ .

A myocardial infarction or serious cardiac dysrhythmia within 3 months would prompt a careful evaluation of the need for the examination and is a reason to monitor the cardiac rhythm during and following the procedure. Bronchoscopy may be carried out within 1 month of a myocardial infarction provided that a strong indication exists [225,226]. Unstable angina or uncontrolled left ventricular failure would clearly necessitate postponement of the procedure.

Thrombocytopenia or any other uncorrected bleeding tendency, including the presence of uraemia (which impairs platelet function), renders biopsy hazardous. As mentioned in the preceding section, transbronchial lung biopsy may be carried out when the need is pressing provided that steps are taken to correct the problem. Thus

6–12 units of platelets should be given for platelet counts of less than  $50 \times 10^9/L$  and haematological advice should be taken about the correction of bleeding diatheses. A blood urea of greater than 11 mmol/L (blood urea nitrogen 30 mg/dL) has previously been regarded as a marker of haemorrhagic risk [233]. More recently, greater tolerance of renal insufficiency has been shown, a serum creatinine of greater than  $260 \mu\text{mol/L}$  (3 mg/dL) being considered a relative contraindication to transbronchial lung biopsy by one group [234]. Such perturbations may lead to the request for a bleeding time, which if greater than 15 min is also regarded as a contraindication until corrected [209], although good data on the positive correlation between bleeding time and haemorrhagic risk in transbronchial lung biopsy are sparse [235].

Fibreoptic bronchoscopy may be carried out in controlled asthma provided that precautions are taken, and this condition should be regarded only as a relative contraindication to the procedure. Severe tracheal stenosis is more safely inspected by rigid bronchoscopy and to take biopsies in an area of critical tracheal narrowing is to court disaster.

### Infection control in fibreoptic bronchoscopy

It has been suggested that for the purposes of infection control in bronchoscopy all patients should be assumed to be potential HIV carriers, so that precautions should be applied routinely [118]; such advice clearly makes good sense.

### Protection of instruments

Fibreoptic bronchoscopes are costly and should be handled only by properly trained staff [231]. One firm of distributors used to be in possession of the wreck of an instrument fused to the inside of its carrying case after the bronchoscopist had made the mistake of leaving it on an intensive care unit only for it to be later removed and placed in an autoclave, as though it had been made of steel!

### Protection of staff

The chance of the spread of HIV infection from saliva is considered to be very small; however, occasional cases of HIV transmission have been reported from the splashing of blood on to broken skin or mucous membranes [236]. Care should be taken with the cricothyroid application of anaesthetic because of the small chance of self-inoculation. Seroconversion following needlestick injury after drawing blood in patients who are HIV or hepatitis B positive is thought to be about 0.9% in the former and 6–20% in the latter, so that bronchoscopists who do not have immunity should receive hepatitis B vaccine [237]. In order to avoid unnecessary risk, it has been recommended

that staff involved in bronchoscopy should wear water-impermeable gowns/aprons, gloves and masks. In addition, goggles or other protective eye-wear should be worn to avoid the theoretical transmission of the virus from contaminated material that might splash into the face of the bronchoscopist from the suction channel of the instrument when the patient coughs. Any accidental exposure to the blood of a patient known to be HIV positive may, after an appropriate risk assessment of the incident, be dealt with by a 4-week course of three antiretroviral drugs according to current published guidelines [238]. All pathological specimens are handled with the usual precautions applied to blood samples, being bagged in plastic before delivery to the laboratory. All disposables are bagged for incineration [239,240]. Contaminated surfaces may be cleaned effectively with a 10% solution of domestic bleach (sodium hypochlorite).

### Protection of patients

It is important that fibreoptic bronchoscopes and their accessories are thoroughly cleaned in order to prevent the transmission of infection [241], particularly as the instruments are used increasingly for diagnostic purposes in susceptible patients who are immunocompromised. Furthermore, potential pathogens identified in bronchoscopic washings may in fact be contaminants if bronchoscopic cleaning techniques are imperfect and this may lead to the inappropriate treatment of patients with potentially toxic antimicrobial agents. *Mycobacteria* and *Pseudomonas aeruginosa* were found to be the organisms most commonly transmitted in one study [241]. The bronchoscope may become contaminated from tap water by environmental organisms such as *M. chelonae*, *M. fortuitum* and *M. xenopi* and by fungi such as *Rhodotorula rubra* and *Blastomyces dermatitidis* [242].

It is most important that fibreoptic bronchoscopes are routinely first cleaned *before* being disinfected, these procedures being carried out by a trained nurse or other assistant both at the beginning of a list and between procedures [242,243]. Removable valves from the proximal end of the suction channel are dismantled and hand-washed and brushed using neutral detergent. The bronchoscopic channel should be similarly hand-brushed with detergent. Prior dispersion of particulate matter from complex components, such as biopsy forceps and cleaning brushes, by placing them in an ultrasonic cleaner with detergent for 10 min has been claimed to be helpful and is often carried out routinely in well-equipped units. It is stressed that these manual cleaning procedures must be carried out before disinfection as some disinfectants fix proteinaceous debris (which may subsequently act as a nidus for infection) and such material is not effectively removed by washing machines. A solution of neutral detergent is also sucked through the biopsy channel several times, between

which a cleaning brush is pulled up and down the channel to remove blood and particulate matter. Further disinfection is usually achieved using a freshly prepared 2% alkaline solution of glutaraldehyde in which modern bronchoscopes and biopsy implements may be totally immersed for 20 min, the solution being first drawn into the suction channel using a syringe. It is now a requirement that glutaraldehyde be used under a fume hood because of its irritant properties and propensity to cause asthma. This part of the process is now frequently carried out in washing machines, although personnel should be aware that these machines may themselves become contaminated; thus they should be regularly serviced and not be considered immune from periodic inspection by the infection control team.

After this cleaning and disinfection procedure has been followed, the shaft of the instrument and its channel are then wiped and rinsed through with sterile water (which does not contain environmental mycobacteria) or 70% alcohol, all parts being well dried before reassembly or storage [244]. North American guidelines for infection control in flexible endoscopy have also been published [245]. Recent evidence has been published showing that many units in the UK do not fully adhere to guidelines on disinfection procedures [243].

When tuberculosis is suspected, immersion of the bronchoscope for 1 h has been recommended [246], although the usual practice of thorough cleaning followed by a 20-min immersion in 2% glutaraldehyde is probably adequate [242,243,247]. *M. avium-intracellulare* is more resistant to glutaraldehyde than *M. tuberculosis* [248] so that when immunocompromised patients are to undergo bronchoscopy, 2% glutaraldehyde immersion of the bronchoscope for 1 h rather than the usual 20 min has been suggested [244]. Earlier publications recommended prolonged immersion of bronchoscopes in glutaraldehyde following their use in HIV-infected patients [239]. However, HIV has been shown to be destroyed by 2% glutaraldehyde within 2 min even in the presence of serum [236]. Hepatitis B virus has similarly been shown to be inactivated by 2% glutaraldehyde in less than 10 min [236].

Stabilized buffered 0.35% peracetic acid solution is a new, less irritant, more rapidly acting and more expensive alternative to 2% glutaraldehyde that is currently undergoing evaluation. Fibreoptic bronchoscopes may be gas sterilized using ethylene oxide but this is rarely necessary and indeed carries the disadvantage of requiring up to 7 days to allow for the dispersal of gas that has become adsorbed on to the plastic parts of the instrument; furthermore ethylene oxide may sometimes cause damage to the shaft of the bronchoscope.

The risk of infective endocarditis in susceptible patients appears to be very low or negligible following fibreoptic bronchoscopy so that antibiotic prophylaxis is not mandatory [249].

**Table 8.4** Indications for rigid bronchoscopy (see text).

### **The place of rigid bronchoscopy under general anaesthesia**

The rigid bronchoscope has by tradition been the instrument of the thoracic surgeon and a postal survey carried out in 1983 found that only 24 of 231 respiratory physicians who responded made use of the rigid instrument [52]. Despite this, the rigid bronchoscope used under general anaesthesia retains an important role (Table 8.4), sometimes because the rigid instrument itself is preferable and sometimes because general rather than topical anaesthesia is indicated [52,250].

The principal advantages of the rigid bronchoscope relate to (i) its wide channel through which large biopsies and foreign bodies can be more easily grasped and removed and (ii) its superior suction capability. It has also been claimed that extrinsic involvement of the carina by nodes can be inferred by using the rigid bronchoscope as a lever. The principal disadvantages of the rigid bronchoscope are its lack of manoeuvrability and the requirement for a general anaesthetic if a particularly unforgettable experience is to be avoided.

Fibreoptic bronchoscopy in children using topical anaesthesia is not only a frightening procedure but may also interrupt normal ventilation significantly, as the bronchoscope acts as a space-occupying lesion in the relatively small volume provided by the child's glottis and trachea, although this spatial problem has been reduced by the availability of smaller, purpose-designed, paediatric fibreoptic bronchoscopes [251–253]. However, these are unsuitable for removing foreign bodies and cannot deal with brisk bleeding. In general, bronchoscopy in the adult or paediatric patient who is uncooperative is best performed under general anaesthesia if a tiresome fiasco is to be avoided.

The rigid bronchoscope was first developed to remove foreign bodies and has retained its pre-eminence in this field [38,255]. Similarly the rigid bronchoscope is necessary for the endoscopic removal of a broncholith. The flexible bronchoscope may be used to remove small foreign bodies that may be beyond reach of the rigid instrument and a number of accessories are available for this purpose [38]. These include wire baskets or claws, with alligator forceps and balloon catheters [38]. The fibreoptic instrument may also be useful if the rigid bronchoscope cannot be used because of trauma to the face or neck.

The emergency treatment of profuse haemoptysis may be delivered using a rigid bronchoscope that provides a channel for stronger suction, enabling the bronchoscopist to pack the bleeding bronchus with gauze tape or to otherwise tamponade it by means of a Fogarty or similar balloon catheter. The fiberoptic bronchoscope suffers from the dual disadvantage of immediate loss of vision with anything more than the most trivial bleed and of a suction capacity that is immediately overwhelmed by a large volume of blood. Nevertheless, when a bleed occurs during fiberoptic bronchoscopy it is possible to tamponade the bronchus with a balloon catheter as previously described on p. 168 [255]. The author has seen torrential bleeding during rigid bronchoscopy result in fatality despite the advantages that this instrument possesses in this situation.

Tumours involving the trachea or protruding above the level of the carina are often anticipated, as a result of the presence of stridor and because of the typical appearance of a flow-volume loop or FEV<sub>1</sub>-time curve. These are better inspected by the rigid instrument as the flexible instrument can cause respiratory embarrassment in the presence of critical airway narrowing, whereas the hollow-tube bronchoscope does not. Biopsies should not be undertaken with either instrument where narrowing is judged to be critical as only a little oedema or haemorrhage may seriously worsen the obstruction. Other serious causes of tracheal narrowing are also best inspected using the rigid instrument, which may also be used to pass a tracheal dilator or in stenting of the trachea or a main bronchus [44]. Rigid bronchoscopy may also be used in the treatment of large airway tumours by laser [42].

## Lung biopsy

Lung biopsy is carried out in order to establish a histological or microbiological diagnosis in a patient with either diffuse or localized lung disease, provided that the diagnosis cannot be established with a reasonable degree of certainty by other less invasive means. The procedure should be undertaken if it is anticipated that the information obtained will usefully influence the management of the patient, either by encouraging the initiation of potentially beneficial treatment or by discouraging potentially harmful empirical therapy.

Lung biopsy may be closed or open. Closed lung biopsy may be carried out percutaneously with various types of needle or trephine by any physician competent in the technique. Nowadays it is more commonly performed by radiologists who are trained to guide the needle to the most appropriate place under fluoroscopic, CT or, in the case of subpleural lesions, ultrasound control [256,257]. In the case of closed lung biopsy, it should be remembered that a negative biopsy of a 'mass lesion' does not always exclude malignancy and that preoperative investigation using these techniques is not necessary if surgical excision will be carried out regardless of a negative result.

Before undertaking any type of lung biopsy it is wise to check the haemoglobin and to request a 'clotting screen' and measurement of urea and creatinine; the patient's blood group should also be determined and serum saved. An uncorrectable bleeding diathesis is a clear contraindication to biopsy (see pp. 169–170). Bilateral procedures are never carried out at the same session because of the risk of double pneumothoraces. Impaired lung function increases the risk of the procedure and a compelling reason would need to be found to justify the risk of lung biopsy in a patient with an FEV<sub>1</sub> of less than 1 L. Other contraindications to closed needle biopsy include uncontrollable cough and pulmonary hypertension.

## Transbronchial lung biopsy

This procedure has been fully discussed in the section on bronchoscopy (see pp. 157–160).

## Percutaneous fine-needle biopsy

Two techniques in use are aspiration biopsy and screw-needle biopsy. Aspiration biopsy needles are, by convention, smaller than 20 gauge (usually 22 gauge) and obtain cellular material for cytological examination, in contrast to the 'cutting' or 'core' biopsy needles described later that are designed to obtain a core of tissue suitable for making multiple conventional histological paraffin sections. One technique employs a thin spinal-type or longer Chiba needle, with an external diameter of approximately 1 mm, that is introduced together with a central stylette into the area under investigation, suction being applied and the needle withdrawn with a small harvest of cellular debris [258,259]. Various designs of circumferentially sharpened needles have been used with lengths up to about 20 cm, similar to those available for lumbar puncture, although modifications such as the provision of a lateral slot towards the tip of the needle may retrieve more material for diagnostic purposes (Fig. 8.8). Many dif-

**Fig. 8.8** Fine percutaneous aspiration needle (above) with a lateral slot towards its tip designed to increase the sample size. Screw-type fine biopsy needle (below) with a coaxial system enabling the screw-like stylette to trap larger clumps of cells.

ferent types of needle have been designed, some relying on a coaxial system in which the lesion is located with a slightly larger outer needle, multiple passes being then made through this with a thinner inner aspiration needle. More specialized needles of the type developed by Nordenstrom that are modifications of this coaxial system are also available [260,261]. These are also thin (1 mm) but differ in that a screw-like stylette traps larger clumps of cells (Fig. 8.8).

These types of needle are used to sample discrete peripheral lesions beyond bronchoscopic vision, more often than not to confirm a diagnosis of neoplastic disease [262]. The size of peripheral lesion that may be successfully biopsied is a function of the skill of the operator and the resolution of the radiographic equipment. Biopsy of lesions greater than 2 cm in diameter should be achievable with a reasonable level of expertise; lesions of 1–2 cm may be attempted but lesions of less than 1 cm require CT or biplanar imaging equipment and a very high degree of proficiency [263]. More centrally placed hilar and mediastinal masses may also be biopsied [264]. Less frequently, needle aspiration has been used in serious and unresponsive cases of pneumonia when the aetiological agent is uncertain [265].

### Techniques

The area of interest is predetermined from recent posteroanterior and lateral chest radiographs and by CT, the latter being helpful in planning the biopsy approach. The patient may be sedated provided that no contraindications exist and is positioned prone or supine according to whether a posterior or anterior approach is planned. The area under investigation is then identified under radiographic control, usually by CT guidance or ultrasound in the case of lesions abutting the chest wall with no separation by aerated lung. Biplanar or C-arm fluoroscopy may also be used to locate the lesion. If single-plane fluoroscopy without a C-arm is all that is available, then the vertical distance between the skin surface and the lesion can be predetermined by measurement on the lateral chest radiograph and this distance measured off against the biopsy needle and marked with either a ligature or plastic clip, so that the needle may be advanced to the correct depth; the area of skin through which the needle will enter is marked under fluoroscopy using a metal pointer and skin pencil. Fluoroscopic guidance may be an advantage in biopsy of lesions in the lower third of the lungs, where respiratory excursions are greater, as it provides imaging in real time.

The area is then cleaned and local anaesthetic (about 10 mL of 1% lidocaine) applied to the skin and chest wall down to the pleura. A nick is made in the skin with a scalpel blade to allow easy passage of the needle. The position of the lesion is again checked fluoroscopically and the needle inserted into the abnormal area, usually using an

approach that is perpendicular to the chest wall and under intermittent fluoroscopic control. Some resistance may be felt when the needle contacts relatively dense tissue such as tumour but this may not be discernible.

In the case of aspiration biopsy of presumed solid lesions, the stylette is removed when the needle tip is judged to abut the edge of the lesion, the bevel of the needle being covered with the gloved finger to reduce the possibility of air embolism. A 10-mL syringe is then attached to it and forceful suction applied as the needle is advanced into the lesion. Suction may be continued as the needle is 'jiggled' up and down a few times and rotated or 'drilled' within the lesion but is turned off as the needle is slowly withdrawn from the chest, the aim being to draw material into the tip of the needle rather than the barrel of the syringe itself [264]. Once removed from the chest, the contents of the needle can be displaced on to a microscope slide either with the needle stylette or by blowing a little air through the needle from the syringe. Some prefer that a cooperative patient should suspend respiration when the needle is being advanced into the lung, while others prefer to permit quiet breathing in order to avoid the risk of a sudden respiratory excursion while the needle tip is in the chest. When fine-needle aspiration is being used to obtain microbiological information in 'difficult' pneumonias, the syringe may be primed with a few millilitres of non-bacteriostatic, sterile normal saline that is expelled into the area of suspicion before negative pressure is applied [265].

The technique of screw-needle (Nordenstrom) biopsy differs in that the biopsy device is a 22-cm needle, the last 1.5 cm of which is screw-like, inserted through a 1-mm diameter, 16-cm cannula that is itself held in a specially designed handle so that the instrument may be manipulated in a narrow X-ray beam without exposing the operator's hand to radiation. The cannula and screw are inserted together, with the screw in the sheathed position. When the edge of the lesion to be biopsied is reached, the screw is rotated clockwise between finger and thumb, drawing itself into the lesion while the rest of the instrument is held in the same position. The cannula is then advanced over the screw and the whole withdrawn together. As with other needling techniques, the manoeuvre and its effect can be safely and conveniently practised using an apple. A technique has been described by which three screw-needle biopsies may be taken with only one passage of the outer cannula [261]. Screw-needle biopsy allows a larger sample to be obtained than is possible with the tip of a standard aspiration needle and firmer more organized tissue to be successfully biopsied, whereas this might not be achieved with aspiration devices.

A chest radiograph is obtained after the conclusion of the procedure to exclude pneumothorax or intrapulmonary bleeding and the patient is advised to report the development of any new symptoms. The film may be repeated at 4 h or the following day as slow pleural air leaks sometimes occur, although this practice is often

omitted unless the patient is symptomatic. Patients who are having fine-needle biopsy carried out on a day-case basis should have the procedure done in the morning in order to allow a period of observation on the ward. They should also have someone to accompany them home and to remain with them overnight, with an agreed hospital point of access should difficulties arise. It is safer for the patient to remain in hospital overnight if these conditions cannot be met.

### Processing the specimen

As with BAL, retrieval of the specimen is only the first stage of the diagnostic process and the most competent technical performance may come to nothing unless there is a good degree of communication and cooperation between the operator and colleagues in the pathology or microbiology departments. The aspirated material should be placed on a labelled slide and spread evenly with the end of a second slide, before being fixed immediately by placement in 95% alcohol in a Coplin jar. Ideally, this should be done under the supervision of a cytologist or, if this is not possible, according to an agreed and tried protocol. For aspiration needle biopsy the cellular contents of the needle may be expelled on to a slide using the syringe. Smears are also made from material adherent to the screw when the Nordenstrom needle biopsy device has been used. Some debris may also be obtained by blowing air through the needle with a syringe. One advantage of having expert and readily available cytopathological comment on the smears is that the biopsy can be repeated at the same session if no neoplastic cells are initially identified in a lesion considered clinically to be a tumour [266]. Few facilities enjoy this luxury.

Where microbiological rather than cytological information is sought the procedure is the same, except that the material obtained is stained and cultured for microorganisms rather than submitted for cytology. Some of the aspirated material (in saline) may be inoculated into appropriate broth or solid media for culture according to microbiological advice and the needle and syringe may also be rinsed out with a liquid culture medium. Appropriate stains may be applied as described on pp. 165–166.

### Complications

#### *Pneumothorax*

This is the most common complication of fine-needle biopsy of the lung, occurring in between one-fifth and one-third of patients [261,263,264]; the sudden onset of sharp chest pain should alert the operator to this possibility. The majority of these pneumothoraces are shallow and require no treatment, but the placement of an intercostal drain may be necessary in 1–13% of cases [261,263,264,267,

268], the incidence of pneumothorax having been found to fall as the experience of the operator increases [261]. It should be borne in mind that the pleura will be punctured more than once if the needle crosses an interlobar fissure and thus the chance of pneumothorax is increased. Biopsy of lesions abutting the pleura rarely causes pneumothorax, although the chance of pneumothorax increases in needle biopsy with increasing distance of the lesion from the chest wall or if the lesion is small so that more needle passes are required to locate it [269]. Some but not all have found that pneumothorax is more likely in the presence of an obstructive impairment of ventilatory capacity [270–272]. When this complication does arise in an emphysematous patient, intercostal tube drainage is more likely to be required [269]. It has been claimed that if the patient breathes pure oxygen before lung biopsy, the frequency of a complicating pneumothorax is reduced [273]. However, Poe and colleagues [274] observed an unaltered risk after breathing oxygen, although the size of the pneumothorax was reduced and the rate of absorption increased. It is the experience of some authors that the rate of complicating pneumothorax may be reduced if the patient lies ‘puncture site down’ for 1 h after the procedure [275]. The equipment necessary for dealing with a pneumothorax should always be available when any form of closed lung biopsy is carried out.

#### *Haemorrhage*

Severe haemorrhage into the lung is the most feared complication of closed lung biopsy. This is rare with fine-needle biopsy, although small haemoptyses are not uncommon and radiographic evidence of a small pulmonary haematoma after the procedure is sometimes seen. Haemoptysis of sufficient size to require treatment is rare [261,262]; the various management options are dealt with in a previous section (see pp. 167–168). Significant bleeding into the pleural space may also occur [276]. Chest wall bleeding is prevented by avoidance of the intercostal arteries, the needle being inserted over the upper margin of a rib, attention also being paid to the surface anatomy of the internal mammary arteries, which run vertically 3–4 cm to the left and right of the sternum, posterior to the costal cartilages.

#### *Air embolism*

Air embolism complicating needle biopsy has been recorded as a possible cause of loss of consciousness, convulsion and cerebral infarction on rare occasions [277–279]. Theoretically it is possible for air to enter a pulmonary vein through the needle if this is unoccluded or for air to pass from a punctured bronchus into an adjacent damaged vein once the needle has been withdrawn, especially if coughing occurs. This potentially fatal complica-

tion, which may be managed with hyperbaric oxygen therapy [278], has been estimated to occur in about 1 in 2000 cases [263].

#### *Tumour seeding*

The possibility that an operable tumour might be seeded into the chest wall or pleura, although apparently remote with fine-needle biopsy, is nevertheless well reported and should therefore be carefully considered before biopsy of an apparently 'operable tumour' [280–283].

#### **Diagnostic accuracy**

A diagnosis is frequently reached in experienced hands. Success or failure depends not only on the nature of the case under investigation (almost always neoplastic disease in the published series) but also on the combined skill and experience of the operator and the cytology service. Those centres with a high level of expertise with the techniques described may obtain diagnostically useful material in 75–95% of cases, the highest yields being obtained in malignant lesions [21,261–263,284,285]. Such results are not achieved when the investigation is undertaken in less than optimal conditions. Thus although false-negative results in neoplastic disease may be only 5 or 6% in the best series, figures that are themselves cause for concern, the rate of false negativity in more usual circumstances may be higher. A large series of 683 patients with solitary pulmonary nodules found a false-negative rate of 18% of 203 patients in whom a diagnosis of malignancy was ultimately confirmed histologically by other means [284]. There was a false-positive rate for malignancy of 1.5% in the same series. A precise histological diagnosis is problematical but it is usually possible to make the distinction between small-cell and non-small-cell lung cancer [286]. The material obtained from fine-needle aspiration of benign nodules is more often undiagnostic, the reported accuracy ranging between 46 and 68% [287].

#### **Contraindications**

Fine-needle biopsy of the lung is contraindicated in patients who are unable to cooperate either as a result of illness or for other reasons. Uncorrected bleeding disorders or other conditions associated with an increased tendency to bleed, such as uraemia or pulmonary hypertension, are also contraindications. The presence of severe respiratory impairment to the extent that even a shallow pneumothorax might be dangerous would present an unacceptable risk. Other contraindications include bullous emphysema, the possibility of the opacity under investigation being either a vascular anomaly or a hydatid cyst, and the use of positive pressure mechanical ventilation.

#### **Mortality**

The reported mortality rate is very low, in the order of 0.1% [262,268].

#### **Cutting-needle biopsy**

Various manually operated cutting needles have been designed to remove a core of tissue from the lung; the modified Vim disposable cutting needle is one example (Fig. 8.9). It is the general view that the use of such wide-gauge needles (approximately 2 mm) is associated with greater morbidity and mortality than fine-needle biopsy, particularly if they are used to obtain tissue from patients with diffuse lung disease. This may be because a specimen of air-filled lung tissue is difficult to obtain with a conventional cutting needle without tearing surrounding lung and disrupting blood vessels in the process. Although some practitioners continue to use these larger manually operated cutting needles, mainly in patients with relatively superficial localized malignant disease, a variety of automated cutting needles that offer a number of advantages have been introduced in recent years [288].

#### **Techniques**

The radiographic determination of the position of the lesion and the preparation of the patient, including positioning under fluoroscopic or CT control, are as described for fine-needle biopsy. If the manual technique is used, the modified Vim biopsy needle (Tru-cut) is inserted in the closed position. Once the tip of the needle has entered the lesion the inner stylet is advanced to its limit using one hand, exposing a 20-mm specimen notch (the 'open' position). While the stylet is held steady in the first hand, the outer cutting sheath is then advanced rapidly over the stylet using the other hand so that the needle is once again closed, this time within the lesion, and the biopsy is secured. The needle is then immediately removed and the

**Fig. 8.9** Tip of cutting biopsy needle in open and closed positions.

specimen retrieved. The manipulations of the needle are carried out either during breath-holding, if the patient is judged able to cooperate, or during normal tidal breathing. The whole manoeuvre, once practised beforehand, need only take a few seconds. Where there is macroscopic doubt about the adequacy of the sample, and provided that there are no complications, the procedure may be repeated once or twice.

A fine-bore (1.2 mm) manually operated cutting needle has also been produced, the design being based on a modified Menghini technique. The needle (Vacu-cut) is inserted through the chest wall in a 'closed' position, after which a central trocar is retracted to induce a partial vacuum in the body of the needle, which is advanced and rotated into the lesion under radiographic control [289].

The first large series of automated biopsies described the use of an adapted 14–20 gauge Tru-cut needle that was single-handedly fired using a spring-loaded trigger device (Biopty) by which the central stylet was advanced by a spring, followed a fraction of a second later by the outer cutting sheath of the needle [290]. This device has the advantage of being easy to manipulate and fire with one hand, leaving the other hand free to hold an ultrasound probe in appropriate cases [290]. Such powered cutting-needle biopsy guns are widely used to obtain tissue from a variety of organs. One of the advantages of such needles for lung biopsy, compared with their non-automated counterparts, is the relatively small diameters available (usually 18 or 20 gauge) that nevertheless produce satisfactory cores of tissue 16 mm in length with a clear-cut edge, the shearing effect being minimal as a result of the very high speed with which the biopsy is taken [288,291].

Samples may be transferred from these needles to a Petri dish containing normal saline and thence to 10% formalin fixative. Staining is carried out in the light of prior discussion with the histopathologist and microbiologist, according to the nature of the case, and as well as haematoxylin and eosin might in appropriate circumstances include auramine, Ziehl–Nielson and silver methenamine stains for acid-fast bacilli, fungi, etc.

At the conclusion of the procedure chest radiographs are taken to exclude pneumothorax, as for fine-needle biopsy.

## Complications

### *Pneumothorax*

As with fine-needle biopsy, pneumothorax is the most frequent complication and has been reported to occur in 11–32% of cases in series that used non-automated cutting needles which crossed aerated lung [292–294]. The lower figure was obtained in those lesions where the vast majority were within 3 cm of the pleural surface [294]. One large

series of 220 biopsies, carried out using the Franklin–Silverman needle, in patients with diffuse disease found pneumothorax in 32% [295]. Complications are unusual in the case of pleurally based lesions, no pneumothorax occurring in 133 such lesions that were biopsied with non-automated large cutting needles in one series [294]. Death as a result of tension pneumothorax has been reported; however, as with fine-needle biopsy it is unusual for intercostal tube drainage to be required [296]. The fine-bore 1.2-mm modified Menghini needle (Vacu-cut) produced pneumothorax in 28% of a small series of 29 patients, three patients (10%) requiring placement of a small-bore tube for drainage [289]. A combined series of automated cutting-needle biopsies of 25 pleural lesions and 32 lesions surrounded by aerated lung produced pneumothorax in 15.6% of cases, active treatment being required in only one (3%) [297].

### *Haemorrhage*

Bleeding is not uncommon and is usually detected as a small haemoptysis or increased radiographic shadowing in the region of the biopsy. Occasionally more substantial bleeds occur [295]. One large study recorded haemoptysis in 18% of 220 biopsies of diffuse disease, one of which was fatal. A more recent series recorded haemorrhage, usually minor, in 20% of cases biopsied for localized disease. Haemoptysis estimated to be more than 50 mL was recorded in 5.6% of a total of 89 patients, one patient requiring a transfusion for a large haemothorax [292]. A review of 13 deaths caused by percutaneous lung biopsy found that 10 followed the use of cutting-needle or trephine (see below) techniques, despite the fact that these procedures accounted for a minority of most large series [298]. It is largely as a result of such sudden and catastrophic bleeds, which once witnessed are not easily forgotten, that the transbronchial lung biopsy technique was developed [299–301]. Such complications probably occur more frequently when the cutting needle is used in diffuse disease and when penetration is deep, although whether it is safer to restrict penetration to 3 cm beneath the pleura (or to 8 cm from the skin surface) is controversial [292,302]. It is intuitive that a more superficial stab is less likely to cause serious harm than a deep one.

### *Miscellaneous complications*

Other complications are uncommon and as described for aspiration lung biopsy. There is a remote possibility of air embolism. The seeding of the needle track by neoplastic cells occurred in 2 of 69 cases of confirmed malignancy (2.9%) in one series and has the potential to convert an operable case into an inoperable one [292]. This complication has been reported more frequently following cutting-needle biopsy than with fine-needle aspiration biopsy.

Infection of the pleural space is a rarely described complication [294].

### Diagnostic accuracy

Cutting-needle biopsy has not usually been recommended for diffuse lung disease because (i) the yield of tissue from non-automated cutting needles has been inadequate for definite diagnosis in one-quarter of cases or more, and (ii) the rate with which serious complications occurs is higher than for alternative diagnostic methods such as transbronchial lung biopsy and thoracoscopic or open lung biopsy [292,300–303]. A small study in which an automated cutting needle was used in 15 patients with diffuse lung disease produced a histological diagnosis in 79%, a 1.2-mm diameter needle being used in 14 of them; a complicating pneumothorax occurred in the one remaining patient (7%) in whom a 2-mm diameter needle was used [304].

There is no doubt that use of the older non-automated cutting needle can achieve a reasonable degree of accuracy in peripheral mass lesions. Comparisons between different series are not necessarily justifiable, but positive yields of 61–96% have been claimed where the lesion was considered malignant [292,296,302,305]. The series claiming the highest positive yield for localized opacities failed to obtain clinically useful information in 8% of cases, the pathological process being declared non-malignant in 18% of 89 patients [292]. A high degree of accuracy has been achieved for lesions that exceed 2 cm in diameter [292]. Lesions smaller than this require a high level of skill and adequate fluoroscopic, CT or ultrasound support. A small series in which the fine-bore 1.2-mm modified Menghini needle (Vacu-cut) was used under fluoroscopic control achieved a positive diagnosis in 89% of 18 malignant pulmonary tumours and in 80% of five non-malignant lesions [289].

The earliest large series of automatic cutting-needle biopsies (Biopsy gun) used ultrasound control to obtain 404 biopsies from a variety of organs including 18 lung biopsies in which the sensitivity was 87.5% for malignancy [290]. Further series using the same or similar techniques supported by ultrasound, fluoroscopic or CT guidance have produced consistently good results for localized lesions of pleura, chest wall, lung and mediastinal contents [288,291]. Although fine-needle aspiration biopsies are very sensitive at detecting neoplastic cells, they are dependent on cytological expertise and are less good at providing a tissue-specific diagnosis, whereas cutting needles provide a core of tissue for both conventional staining and immunohistochemical methods and are more likely to provide information about the precise pathological process in both benign and malignant disease, including lymphoma and KS [287,291,297]. A retrospective study of CT-guided transthoracic biopsy com-

pared the use of an 18-gauge automated cutting needle gun and a 20-gauge aspiration needle and concluded that the cutting needle increased diagnostic accuracy with no obvious increase in complication rate [306].

### Contraindications

The contraindications to cutting-needle biopsy are the same as those listed under fine-needle biopsy.

### Mortality

The majority of reported deaths that have occurred in patients as a result of percutaneous lung biopsy have been caused by various types of non-automated cutting needle, and have been a consequence of sudden and massive endobronchial haemorrhage. Various published series using different types of cutting needle (Vim–Silverman, Franklin–Silverman, Vim disposable, Jack) reported four deaths in 1079 patient procedures, giving a mortality rate of 0.37% [292,295,302,305,307–312]. The largest single series of modified Vim (Tru-cut) cutting-needle biopsies recorded two deaths in 382 procedures, giving a mortality rate for this implement of 0.52% [307]. In addition, there are a number of case reports of deaths including two procedures that were carried out for diagnostic purposes in peripheral mass lesions where both of the patients died from haemorrhage [298].

### Drill or trephine biopsy

A mechanically driven rotating cutting needle designed to biopsy various tissues was first described over 50 years ago. In the thorax this technique was confined to biopsy of localized lesions in the lung periphery and pleura until Steel and Winstanley [313], using modified apparatus, published the results of 38 drill biopsies carried out in patients with diffuse lung disease, a positive diagnosis being made in about 71%. The technique has a small and dwindling number of devotees, having been largely supplanted by transbronchial or thoracoscopic biopsy in diffuse disease and by the more modern automated cutting or aspiration needle methods in the case of localized disease.

### Technique

Steel's technique uses a Desoutter pneumatic drill (Fig. 8.10) driven by air compressed to 690 kPa (100 lb/in<sup>2</sup>) supplied from a standard cylinder via a reducing valve. This rotates a 3-mm external diameter trephine with a sharpened cutting edge and internal rifling. The speed of rotation at this pressure is about 15000 r.p.m., so that the cutting edge moves at a speed of 1.6 m/s as it slices through lung. The patient is prepared as described for

Fig. 8.10 Pneumatic trephine biopsy drill.

fine-needle biopsy, except that where the lesion is diffuse it is convenient to carry out the procedure with the patient sitting and leaning forward with arms resting on a support. The eighth intercostal space posteriorly in the region of the tip of the scapula may be used. The skin must be marked if a localized lesion is to be biopsied, and in such cases the procedure is carried out using intermittent fluoroscopy with the patient in either a prone or supine position [314]. The lesion has to be within about 4 cm of the visceral pleura because the hollow trephine is only 7.5 cm long (compared with 13.5 cm for a Tru-cut). The skin is prepared and local anaesthetic applied down to the pleura as previously described. The high-pitched noise that the drill makes when running is then demonstrated to the patient in order to avoid causing undue alarm. The trephine is flushed with 3.8% sodium citrate contained in a 20-mL syringe; if microbiological studies are required, normal saline may be used, about 5 mL being left in the syringe [313]. A small skin incision is made with a scalpel and the trephine with stylet in place is advanced to the pleura. Its position should be checked fluoroscopically in the case of localized lesions. If the position is judged to be satisfactory, the stylet is removed, the lumen of the needle being occluded with the gloved finger, and the drill is attached by its Luer fitting. Some authors found modifications helpful to prevent the slippage that may occur with the Luer fitting when the drill is in action [296,315]. Once the drill, which is not sterile, has been handled, a 'no-touch' technique has to be followed to prevent contamination of the trephine. Unless a gloved assistant is used, this involves the use of another sterile trephine if the procedure has to be repeated.

The patient is asked not to move, cough or breath deeply while the drill is in action. The drill is operated by pressing a lever and the trephine advanced 3–4 cm over the space of 2–3 s. The drill is then disconnected, being replaced with the 20-mL syringe to which suction is applied as the trephine is withdrawn from the lung. The liquid in the barrel of the syringe is used to eject the sample into a Petri dish, and from thence it is placed in for-

malin fixative for staining according to prior discussion with the pathologist. Any small pieces of tissue and residual saline may be submitted for microbiology and/or cytology as described above for the other biopsy procedures. A chest radiograph is obtained routinely at the end of the procedure in order to exclude haemorrhage and pneumothorax, as with other types of lung biopsy.

### Complications

The same complications occur with drill biopsy as for fine-needle aspiration and cutting-needle biopsy. Pneumothorax occurs with a reported frequency of 30–40% [300], although one study found pneumothorax in only 7% of 190 procedures [316]. These required placement of an intercostal drain in 40–60% of cases [314,316]. Substantial haemoptyses were uncommon, occurring in about 2% of cases, but as with other forms of percutaneous lung biopsy fatal haemorrhage may occur, albeit rarely [21,316,317]. Minor haemoptysis occurred in 7% of procedures [316]. As with cutting-needle biopsy, needle track spread of tumour has been described [313,314].

### Diagnostic accuracy

In practiced hands, adequate material has been obtained from drill biopsy in over 80% of cases [300,316], and claims have been made that the size of the specimen is superior to that obtained from any other type of percutaneous biopsy and that lung architecture is better preserved. Those series that compared the diagnostic yield of drill biopsy with transbronchial lung biopsy and cutting-needle biopsy (Vim–Silverman needle) obtained better specimens and a commensurately higher diagnostic yield with the drill, which was claimed to be preferable to earlier manually operated cutting needles for diffuse pulmonary disease and in patients who had large solid mass shadows within 4 cm of the pleural surface [296,318]. However, the development of modern automated cutting needles and thorascopic lung biopsy techniques have largely negated these advantages.

Three large series comprising 339 patients reported diagnostic results in about three-quarters of all cases, of whom almost 70% had 'diffuse disease' [313,314,317]. An Indian study of 161 patients achieved a histological diagnosis in 91% [316].

### Contraindications

These are no different from those listed for fine-needle biopsy.

### Mortality

Deaths resulting from trephine biopsy have rarely been

reported, a figure of about 0.5% having been obtained from a review of published data on drill biopsy for diffuse disease [300,316]. It has generally been supposed that morbidity and mortality is less when the drill is used to sample more localized and superficial disease processes.

## **Open and thoracoscopic lung biopsy**

### **Open lung biopsy**

Open lung biopsy is carried out under general anaesthesia through a thoracotomy. Rather than carry out a full posterolateral incision of the type used for pneumonectomy or lobectomy, most surgeons carry out a so-called 'limited thoracotomy', making their incision in the fourth or fifth intercostal space anteriorly. Other prefer to make a small incision anteriorly in the second or third intercostal space as advocated by some authors for mediastinotomy, finding that this approach allows access not only to all lobes but also to the hilum and anterior mediastinum [319,320]. The surgeon is able to inspect the lung and choose the site thought most likely to yield diagnostic information. It has been recommended that where disease is radiographically diffuse, a site of apparently 'average' involvement should be biopsied; and when disease is advanced, a macroscopically less involved site should be sampled. This approach avoids the submission of a piece of 'honeycombed' lung that on microscopic examination may show only end-stage fibrotic change, with no clues as to the original pathological process. The tip of the lingula and the middle lobe are if possible avoided, being considered less likely to be representative than other parts of the lungs and frequently showing inflammatory changes or fibrosis due to previous and unrelated inflammatory episodes. HRCT may help the physician decide which area of lung should be sampled.

Once a site has been chosen for biopsy, the anaesthetist gently inflates the lungs and the surgeon clamps and excises the portion of lung required and immediately places half to two-thirds of the sample in formalin fixative, thereby avoiding atelectasis [300]. As with any form of lung biopsy, whether percutaneous or open, the diagnostic yield is heavily influenced not only by the sampling techniques but also by the skill and care with which the tissue is subsequently handled and examined. In the author's view no open lung biopsy material should be submitted for laboratory examination without prior discussion with the histopathologist and microbiologist concerned, so that the specimen can be handled according to a protocol that may vary according to the clinical circumstances of each case. Without such discussion, the patient may be submitted to a potentially hazardous procedure with a suboptimal chance of the correct diagnosis being reached. In addition to haematoxylin and eosin, histological stains may include PAS, van Gieson and Prussian Blue; stains for organisms include Gram, auramine,

Ziehl-Nielsen, Gomori's methenamine silver, Giemsa, etc. according to circumstances.

The remaining piece of lung tissue may be submitted unfixed for further microbiological studies, including immunofluorescent tests where appropriate, one portion being ground up and cultured under aerobic and anaerobic conditions for bacteria, mycobacteria and fungi. Another portion may be placed under 4% glutaraldehyde for later electron microscopic studies and a further piece stored at  $-60^{\circ}\text{C}$  for any examination that may be considered helpful later, such as further immunofluorescent testing and viral studies [300].

The surgical procedure for open lung biopsy is relatively minor and the patient may be able to leave hospital within 3–4 days if the underlying condition permits. The 30-day mortality rate in a large series of over 500 cases was 0.2%, with no deaths if extensive carcinoma is excluded [300]. The complication rate from a review of several large series was 7% and mainly resulted from inadequate postoperative intercostal tube drainage. A high diagnostic yield in excess of 90% is usually claimed [134,300,321].

### **Video-assisted thoracoscopic lung biopsy**

This is a thoracic surgical procedure that is an acceptable alternative to open lung biopsy, having the principal advantage of being less invasive [17]. It is carried out in operating theatre conditions, under general anaesthesia and with single-lung ventilation, allowing the lung under thoracoscopic examination to be collapsed so that it can be displaced for a good view. The patient must therefore have sufficient pulmonary reserve to maintain adequate oxygenation with single-lung ventilation and the procedure cannot be carried out on sick hypoxic patients in respiratory failure without significant mortality, as indeed is also the case for conventional open lung biopsy [17]. Three ports of entry are commonly used: one for the thoracoscope, which carries the video camera attachment; one for a linear stapler device, which allows a large sample of lung to be secured for biopsy; and a third to allow instrumentation to remove the specimen. The procedure may not be possible in the presence of pleural adhesions. When compared with open lung biopsy, video-assisted thoracoscopic lung biopsy has been shown to provide specimens of equivalent volume, to have equal diagnostic accuracy, to be as rapid and to have no additional complications, the duration of pleural drainage and hospital stay both being reduced [322–324], although at greater cost [325]. Prior to the availability of video-assisted thoracic surgery and linear staplers, thoracoscopically guided lung biopsy was carried out with the conventional thoracoscope, the biopsy being obtained with forceps and the site being sealed with electrocautery [326], a technique generally regarded as being more likely to result in air leak.

### Is a lung biopsy necessary?

Patients are considered for lung biopsy when they are found to have a chest radiographic abnormality that demands an accurate diagnosis which cannot be reached by other less invasive means. The radiographic shadowing may be diffuse, such as occurs in sarcoidosis or cryptogenic fibrosing alveolitis, or localized, as in the case of peripheral mass shadows situated beyond bronchoscopic vision.

#### Diffuse disease

Lung biopsy is only indicated if the result of the investigation is likely to alter the subsequent management of the patient to his or her benefit. Accurate diagnosis need not improve survival to be regarded as beneficial; thus histological evidence of lymphangitis carcinomatosa may, by removing doubt, place the management of an individual case on a firm footing and allow adequate palliative measures to be taken with confidence.

Not infrequently in diffuse disease, the diagnosis can be made beyond reasonable doubt without recourse to lung biopsy. Such is the case in a patient with the syndrome of erythema nodosum and bilateral hilar lymphadenopathy who develops a diffuse pulmonary infiltrate in the absence of crackles or finger clubbing. The likelihood of sarcoidosis in this clinical context is so high that histological proof may be considered superfluous. Similarly, a patient with a clear occupational exposure to asbestos dust who develops clubbing and crackles with chest radiographic and physiological changes consistent with asbestosis may require no further diagnostic confirmation. Likewise, the diagnosis is sufficiently evident when exposure to some recognized cause of extrinsic allergic alveolitis, such as a budgerigar, is associated with typical features, including breathlessness, upper zone crackles and mid-inspiratory squawks, physiological evidence of lung restriction, reduced gas transfer, the usual radiographic features and the finding of allergen-specific precipitins in the serum. Chronic eosinophilic pneumonia may also present with sufficiently typical features to allow a non-invasive diagnosis to be made [327].

Lung biopsy becomes necessary in diffuse disease when there is doubt about the diagnosis and when the physician is reluctant to commit the patient to empirical treatment, which may itself be associated with morbidity, without a firmer knowledge of the underlying pathology and the likelihood of a response. Such may be the case in those patients in whom the probable diagnosis is sarcoidosis who may have some degree of effort intolerance, absent digital clubbing, no crackles, a variable degree of restrictive or obstructive impairment of ventilatory capacity and reduced gas transfer factor, diffuse pulmonary radiographic shadowing, with or without hilar lym-

phadenopathy, and no history of erythema nodosum. In such a situation the physician may feel that although the clinical probability of sarcoidosis is high, the diagnosis should be histologically confirmed prior to treatment with corticosteroids.

In cryptogenic fibrosing alveolitis, the decision about whether to biopsy is likely to be influenced by various factors, including the patient's age and general state of frailty. There will be reluctance to submit an elderly and breathless patient, whose life expectancy is short, to an unpleasant invasive procedure when the diagnosis is firmly supported by a typical history, physical signs and chest radiographic, lung function and HRCT findings, especially as the likelihood of response cannot be predicted accurately from histology so that corticosteroids will be tried anyway. However, there is no doubt that corticosteroid or other immunosuppressive treatment can be used with greater conviction in the light of a firm histological diagnosis and therefore this is more likely to be sought in the younger patient, who in the event of failure of treatment and progression of disease may become a candidate for a lung transplant.

Rare conditions that may be associated with diffuse pulmonary shadowing, such as Langerhans' cell histiocytosis, alveolar proteinosis and the pulmonary vasculitides, may well go undiagnosed without histology, leading to appropriate treatment being omitted or at best given on an empirical basis with no very clear idea of the likely prognosis.

A further important clinical situation encountered with ever-increasing frequency is that of the patient who is immunocompromised either as a result of AIDS or as a consequence of receiving immunosuppressive therapy for a variety of conditions, such as tissue transplantation, leukaemia or lymphoma (see Chapter 52). When strenuous therapeutic efforts are being pursued, it becomes important to know whether diffuse pulmonary shadowing is a consequence of opportunistic infection or, in the case of neoplastic disease, whether it may be accounted for by a recurrence of the disease itself or by an adverse effect of a cytotoxic drug. Patients with AIDS often present with perplexing pulmonary manifestations of their underlying disease. Although most diffuse pulmonary infiltrates in this group may be diagnosed by fiberoptic bronchoscopy with lavage, brushings and transbronchial biopsy, about 10% may undergo open lung biopsy in the following circumstances: (i) if the bronchoscopy is non-diagnostic, especially if the patient's condition is deteriorating clinically or radiographically; or (ii) if the patient is failing to respond to treatment despite bronchoscopy that has been diagnostic, provided that the patient is not in respiratory failure or being mechanically ventilated (both of which carry a high mortality and contraindicate open lung biopsy) [328,329]. The operative mortality has been reported to be less than 8% in these circumstances [318].

Others have also found a high diagnostic yield with low morbidity for open lung biopsy in patients with HIV infection and AIDS in whom bronchoscopy was non-diagnostic, also finding that the results significantly affected management [330].

It is not uncommon for extensive bilateral radiographic 'honeycombing' to be encountered for the first time in an elderly patient who may or may not have been treated on an empirical basis over many years without a histological diagnosis ever having been established. The probability of useful information being derived from an invasive procedure in such a case is slim since the histology is likely to be that of end-stage, 'burnt-out', fibrotic disease, perhaps with no clue as to the original pathological process.

Therefore, in all cases that show diffuse pulmonary radiographic shadowing a decision has to be made about whether the patient is best served by empirical treatment based on clinical probability or whether some form of invasive lung biopsy should be used to make the diagnosis firm.

#### **Localized disease (including coin lesions)**

The often solitary peripheral pulmonary lesion (coin lesion or solitary pulmonary nodule) provides another common diagnostic dilemma in which curiosity and enthusiasm should once again be restrained by the prime consideration as to whether the result of a biopsy will influence management. The question that should always be asked is 'What am I going to do if the result of the biopsy is non-diagnostic?' If the answer is 'Ask a surgeon to take it out', then why biopsy in the first place?

The immediate consideration is whether the lesion is a malignant neoplasm rather than a benign tumour or some form of inflammatory disease. Unless there is good evidence to the contrary, such as old chest radiographs that show an identical appearance, then the lesion is best assumed malignant until proved otherwise. A North American study of 40 such patients (mean age 65 years) with solitary pulmonary nodules (defined as rounded lung opacities 3 cm or less in diameter) found that 53% were malignant, over 90% being surgically resectable [331]. CT with contrast may be helpful in such lesions, as malignant tumours can be relied upon to enhance by 20 Hounsfield units, the sensitivity of this test at this level of enhancement approaching 100% [332]; this finding should therefore encourage surgical removal where feasible. Unfortunately a non-enhancing lesion cannot be relied upon to be benign, the specificity of the test being about 78% [332]. Although the published results of various methods of percutaneous biopsy usually claim high positive diagnostic yields, it must be realized that even in the most expert hands false-negative results may occur in patients with neoplastic disease unless sufficient tissue is obtained to enable the pathologist to diagnose a specific

benign process; thus if a decision is taken to withhold surgical excision on the basis of a negative percutaneous or transbronchial biopsy, a variable number of patients with potentially treatable disease may be denied a chance of cure and therefore follow-up in such cases should be very careful.

One approach to the patient with a peripheral mass lesion, in whom non-invasive tests have provided no support for a benign process, who has no evidence of metastatic disease (including CT of the thorax and abdomen) and who is otherwise considered fit for resective surgery, is to advise thoracotomy directly, without first having to submit to a percutaneous biopsy procedure with its additional risks, including that of converting a curable tumour into an incurable one as a result of needle track seeding of neoplastic cells to the chest wall or pleura [280–283,292]. This approach would appear the most prudent for the patient aged 45 years or over with a lesion 3 cm or more in diameter [333]. Occasional exceptions to this rule may have to be made: if it is decided that thoracotomy would for various reasons carry a high risk for an individual patient and the surgeon will only accept that risk if the diagnosis is firm; or if a radiotherapist for various reasons feels constrained not to treat without histological proof of tumour. It must be clear in such situations that the surgeon or radiotherapist will not be inclined to treat anyway, even if the biopsy procedure is negative, since in this case the procedure will have been unnecessary.

The other approach is one of observation, which is reasonable in a young non-smoker with no previous chest radiographs and a well-defined lesion less than 2 cm in diameter. Such lesions are likely to be benign and may be followed up with serial films unless they are found to enhance on CT. In other patients, an old chest radiograph showing that a nodular opacity has remained unchanged for 2 years is helpful as the lesion is likely to be benign. Benign lesions characteristically have a doubling time that exceeds 400 days [334]. It is a useful rule of thumb that a mass has doubled in volume when its diameter has increased by 25%, so that a lesion is likely to be benign if its diameter is increasing by less than 25% every 18 months. Certain patterns of central calcification have also been associated with a benign process but eccentric areas of calcification do not rule out malignancy [334,335].

#### **Which type of lung biopsy procedure?**

Once it has been decided that tissue is required in order to manage a patient optimally, it then becomes necessary to decide which of the various procedures available should be used: transbronchial, fine-needle aspiration, cutting needle, drill, open or thoracoscopic lung biopsy (Fig. 8.11). It has to be accepted that there is a lack of consensus in this regard and that the results of some published series show

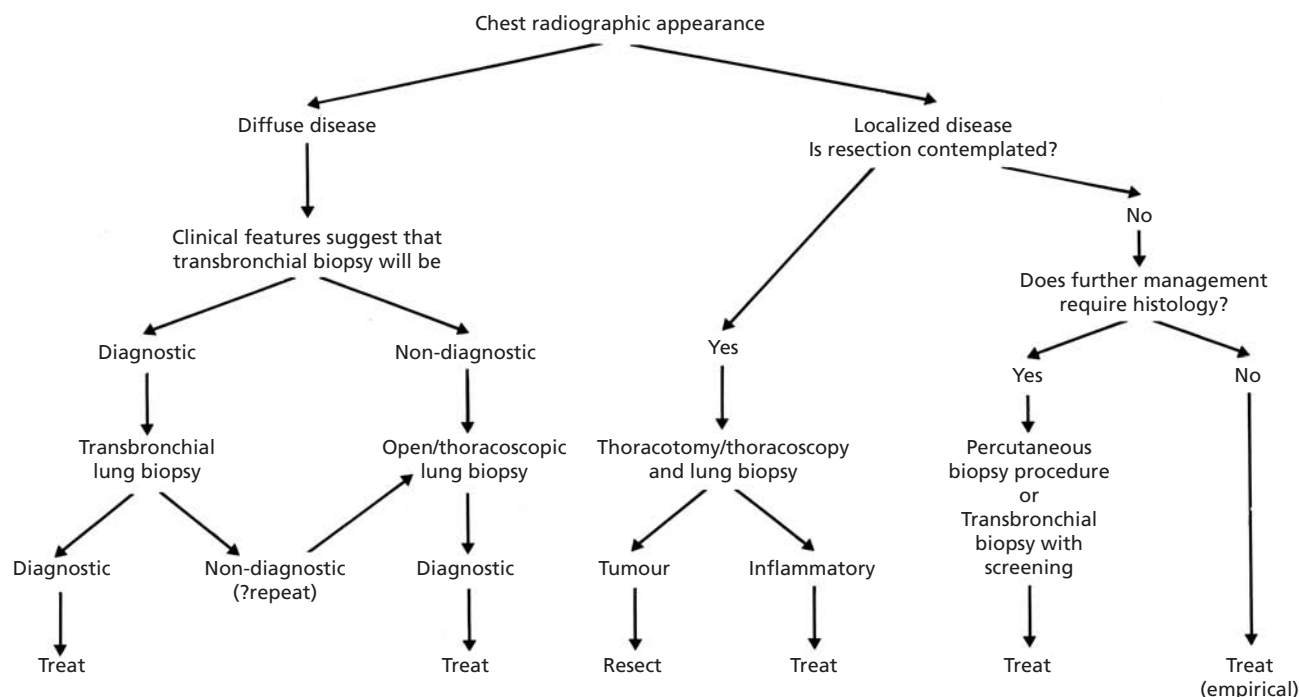

Fig. 8.11 Decision tree for lung biopsy.

a high degree of sensitivity for a particular test that may not necessarily be reproduced in another centre. Nevertheless, some observations of a general nature can be fairly made. Invariably the choice of biopsy procedure is influenced by the likely diagnosis and whether the disease is diffuse or localized.

### Diffuse disease

Some diffuse histopathological processes are so characteristic as to allow a diagnosis to be made from only a small piece of tissue. Thus in the case of diffuse disease in which sarcoidosis is considered probable, transbronchial lung biopsy is the technique of choice and is likely to produce a positive yield [336]. Percutaneous needle biopsies are less favoured in diffuse disease for various reasons. Fine-needle aspiration has been developed primarily for harvesting clumps of cells from solid lesions and can give no idea of lung architecture. Cutting-needle biopsies are also better suited to sampling solid, relatively superficial lesions and although lung tissue can be obtained in diffuse disease it may be torn or distorted (especially with non-automated methods); furthermore, the morbidity of the procedure exceeds that of transbronchial lung biopsy [300], which is preferred in diffuse disease with highly pathognomonic histology. Diffuse disease other than sarcoidosis in which transbronchial biopsy may produce a good yield includes lymphangitis carcinomatosa, *P. carinii* pneumonia (although BAL alone is usually adequate),

eosinophilic granuloma, alveolar proteinosis and pulmonary haemosiderosis. The mortality figures for transbronchial lung biopsy are likely to be skewed by its use in iller patients than tend to be subjected to cutting-needle biopsy and it is generally held that the passage of cutting biopsy needles through aerated lung exposes the patient to greater hazard than transbronchial lung biopsy [307]. Although trephine biopsy delivers a more representative core of tissue than transbronchial lung biopsy, it also carries a higher morbidity than transbronchial biopsy when used to sample diffuse disease. Despite producing good results in well-practiced hands, it is no longer widely used and for peripheral lesions where histology, rather than cytology, is required has been overtaken by automated cutting-needle biopsy using fluoroscopic, CT or ultrasound control.

Open or thoracoscopic lung biopsy is appropriate when investigating diffuse disease in which either transbronchial biopsy has failed to establish the diagnosis or the clinical features suggest from the outset that a larger piece of tissue might be required. This is often the case with disease in which the histological features are more variable, such as cryptogenic fibrosing alveolitis (idiopathic pulmonary fibrosis), in difficult cases of suspected extrinsic allergic alveolitis, and in the pulmonary angitis and granulomatoses.

Open lung biopsy has the twin disadvantages of requiring general anaesthesia and being painful. Although the mortality of the procedure is reportedly greater than that for transbronchial lung biopsy and other closed procedures [300], such reports are likely to be distorted by the

surgical convention of using '30-day mortality' figures and by bias resulting from iller patients being submitted to the open procedure than is the case with closed procedures such as transbronchial biopsy. Open lung biopsy has the advantage of being almost entirely free from the hazard of massive and uncontrollable intrapulmonary haemorrhage, which may rarely complicate all closed lung biopsies. Nowadays, video-assisted thoracoscopic lung biopsy is increasingly favoured because large samples of lung tissue may be satisfactorily obtained with reduced morbidity.

### Localized disease

When disease is localized and peripheral, surgical exploration using an open procedure is usually indicated for both diagnosis and treatment as discussed above. If for some reason this approach is not possible, then the choice of biopsy technique depends to a large extent on individual preference and experience. The choice lies between fine-needle aspiration biopsy, cutting-needle biopsy, drill biopsy and transbronchial lung biopsy/needle aspiration under fluoroscopic control. All these procedures have been described in the preceding sections. It is again stressed that the practical procedure of obtaining the specimen, although clearly of crucial importance, is only one step towards a diagnosis; small specimens, such as the clumps of cells obtained with a fine needle, require expert cytopathological handling with a good level of cooperation between clinician and pathologist.

### Biopsy of the pleura

The pleura is usually biopsied as a closed procedure; less frequently biopsy may be carried out under direct vision at thoracoscopy or as an open procedure at thoracotomy.

### Needle biopsy

This is usually carried out with an Abrams punch [337] (Fig. 8.12), which is advanced through a small incision in the skin and intercostal muscle, with gentle but sustained pressure, using a clockwise–anticlockwise rotatory movement until 'give' is felt, according to the technique described in Chapter 43. This procedure is more easily

carried out in the presence of a pleural effusion, which provides the operator with the welcome reassurance that a good site was chosen. Sometimes needle biopsy may be attempted in the expectation of finding a pleural effusion only to meet the resistance of a grossly thickened pleura. It is generally possible to penetrate such pleural thickening using a rotatory movement to the point of give, without damaging underlying lung, as the tip of the Abrams biopsy punch is relatively blunt. Once this point has been reached it is easy to withdraw the needle slightly with firm pressure on the side of the open biopsy notch so that a pleural sample can be ensnared and removed, usually yielding neoplastic tissue. Some operators may prefer to use a Cope needle [338] or a disposable modified Vim-type cutting needle [339] (Tru-cut, see Fig. 8.9) in this situation, although the sharp tip of the latter may be more likely to puncture underlying lung.

### Complications

The commonest complication is a shallow pneumothorax, usually resulting from the ingress of some air through the biopsy needle or, less commonly, as a result of injury to the underlying lung [340]. Other complications of inappropriately directed needles include haemothorax, which may be massive if an intercostal artery is damaged [341]. Cases of intercostal artery aneurysm and arteriovenous fistula have also been described [341,342], as have injuries to other viscera including the spleen, pancreas and diaphragm. As with any thoracic paracentesis, it is possible for infection to be introduced causing empyema; in the case of malignant effusions, neoplastic cells may be seeded along the needle track [343].

### Diagnostic yield

In patients who are subsequently shown to have a neoplastic cause for a pleural effusion, a positive yield from pleural biopsy is found in 40–70% of cases, the usual diagnostic yield being about 50%. The chance of a positive result is increased by multiple biopsies, pleural fluid cytology and, if results are initially negative, later repeated attempts at pleural biopsy [344–349]. Such positive biopsies usually indicate secondary pleural involvement by tumour. Mesotheliomas may occasionally be diagnosed on needle

Fig. 8.12 Abrams pleural punch.

biopsy material, although this is not easy on a small sample and subsequent postmortem material may show metastatic adenocarcinoma or some other tumour.

When a pleural effusion is due to tuberculosis, the needle biopsy may show consistent granulomatous inflammatory changes or result in isolation of tubercle bacilli in 50–88% of cases, although by no means all cases show caseation, Langhans' giant cells and acid-fast bacilli [344–346,350]. The pleural biopsy in rheumatoid disease may show characteristic changes but more often than not the findings are non-specific [351].

### Simple (conventional) thorascopic biopsy

The principal use of the thoracoscope in the early part of the twentieth century was to allow the operator to divide pleural adhesions, by cutting or electrocautery, so that an artificial pneumothorax could be satisfactorily induced in the era before the antibiotic therapy of tuberculosis. Despite its invention by a physician, thoracoscopy was abandoned by chest physicians in English-speaking countries as effective antituberculous drugs were developed. However, the necessary skills were preserved by thoracic surgeons and also by respiratory physicians on mainland Europe and thoracoscopy began to be adopted increasingly by these groups as an investigative procedure, at first mainly in cases of undiagnosed pleural effusion [352]. Ordinarily, this problem is tackled first with pleural aspiration and closed-needle biopsy of the pleura, as described above, and it is in the 25–30% of patients in whom the diagnosis remains elusive that thoracoscopy may be undertaken in order to identify the local cause while avoiding the need for thoracotomy [353].

In recent years, thoracoscopy has undergone a revival as a result of improvements in the design of the conventional instruments used by both physicians and surgeons and also with the invention of the videothoracoscope. With its miniaturized video camera and fibreoptics, this device has enabled the thoracic contents to be displayed with great clarity on a video screen, thereby enabling the operator and assistant to carry out complex intrathoracic surgery through three small ports without recourse to conventional thoracotomy (see Fig. 44.15). This video-assisted thorascopic surgery has been referred to in the sections on lung biopsy (see p. 179) and remains firmly within the province of the thoracic surgeon, whereas simple or conventional thoracoscopy may be carried out under local anaesthesia and in an endoscopy suite and is being increasingly taken up by physicians.

### Technique

Thoracoscopy may be carried out, with the help of an assistant, under local anaesthesia using 10–20 mL of 1%

lidocaine. Premedication with atropine is usual and sedation with an agent that also produces amnesia, such as midazolam, is considered helpful. Intravenous access is set up, supplemental oxygen given and pulse oximetry recorded. The patient may be positioned in the lateral decubitus position with the healthy side down, the upper arm being cradled in abduction by a support. The dorsal decubitus position may also be used. Any pleural fluid first has to be completely drained in 250-mL aliquots, an equivalent amount of air being allowed to enter the pleural cavity under negative pressure following each aspiration so that the lung falls well away from the chest wall in order to allow full inspection of the pleural cavity. Such drainage can be achieved with a 2–3 mm diameter trocar with combined tap and both sharp and blunt obturators for easy passage and the removal of debris [354]. It is safest to check radiographically that the lung has fallen away from the chest wall before proceeding to the next stage and it may be convenient to carry out the drainage and collapse procedure the day before thoracoscopy.

Next, using blunt dissection, the drainage trocar is removed and replaced with a 5–7 mm thorascopic trocar and cannula in order to allow passage of the thoracoscope itself. This is usually in the mid-axillary line in the sixth or seventh intercostal space when pleural effusions are being investigated. Any pleural fluid remaining in dependent zones can then be aspirated by a small plastic tube introduced through this cannula, enabling the thoracoscope to be passed with good vision. An artificial pneumothorax may be similarly induced in cases where no pleural fluid is present, although care has to be taken not to damage the lung and attempts may be foiled by the presence of pleural adhesions [354].

Whereas the earlier Stortz rigid thorascopes were 11 mm in diameter, modern instruments are much smaller and have excellent optics. Thus a 4–7 mm diameter thoracoscope may be easily introduced into the pleural cavity through a small thorascopic cannula. Angled-vision thorascopes are essential in order to view the pleural cavity as fully as possible, in the fashion of a submarine periscope. 'View-ahead' instruments are also used to enable biopsies to be taken through a single port of entry. Sometimes it may be desirable to fashion a further port of entry using a second 5-mm trocar, the entry position being chosen by depressing an appropriate-looking intercostal space while viewing the inside of the chest wall through the thoracoscope. A second entry point may be useful in obtaining a biopsy from a point that is relatively inaccessible to the thoracoscope, acute angulation of which tends to produce pain by pressing up against the adjacent ribs. This second port may then be used to introduce a 5-mm forceps, which is guided under direct vision from the thoracoscope. The second port may occasionally also be useful as a channel for the introduction of an electro-

cautery loop, which can be used to divide pleural adhesions where these are hindering progress in some way.

Pleural biopsies may be taken with either optical forceps, using a single port, or larger forceps, using a second port of entry as described above. Care is taken to avoid the intercostal vessels when performing the biopsy, especially where the pleura is thin. Most lesions are found on the parietal pleura and multiple biopsies may be taken. In the unusual case where only visceral pleural lesions are found, one or two biopsies may be taken and any air leak or bleeding minimized by use of electrocautery forceps or YAG laser, if available [354]. Intercostal bleeding may be similarly dealt with or may be tamponaded with an epinephrine-soaked sponge through the second port. Insertion of a chest drain with suction to bring the lung rapidly up against the chest wall has also been found to be effective [354].

### Yield

Thoracoscopy is a useful method for diagnosing pleural malignancy that has been missed on pleural fluid cytology and closed-needle pleural biopsy. In a series of 161 patients with pleural effusions, 69% of 35 patients with two or more non-diagnostic pleural aspirations and 60% of another 41 patients with negative closed-needle biopsies were found to have pleural malignancy at thoracoscopy [355]. The procedure was sensitive for diagnosing malignancy, finding it in 95% of cases when this disease was present, with 100% specificity (i.e. no false positives for malignancy) [355]. In a series of 173 patients with pleural effusion due to malignant mesothelioma, a diagnosis was made thoracoscopically in 98% [356].

Thoracoscopy is also a reliable method for diagnosing pleural tuberculosis, although usually this is unnecessary as the yield from closed-needle biopsy is high (see above) [357]. Occasionally rheumatoid pleural effusions present diagnostic difficulties, in which case thoracoscopy may be performed; characteristic granular parietal pleural changes have been described, this material also showing characteristic histology [358]. Thoracoscopic mediastinal biopsy may provide a histological diagnosis in 86% of patients with mediastinal masses [359].

### Thoracoscopic talc pleurodesis

The thoracoscope may also be used therapeutically in malignant pleural effusions in order to obtain a pleurodesis by carrying out talc poudrage, 4.5g of pulverized sterile talc being insufflated under direct vision using a talc atomizer. A 28–30 French gauge intercostal tube, with side-holes cut along its length, can then be passed through the seventh intercostal space in the mid-axillary line and directed along the costovertebral gutter towards the lung

apex under thoracoscopic control, being kept in for a few days until drainage is complete [354,360]. Talc insufflation has been shown to be superior to both tetracycline and bleomycin in reducing the natural tendency for a malignant effusion to reaccumulate [361].

### Complications

Thoracoscopy itself appears to carry little risk, induction of a pneumothorax being well tolerated [362]. Air leaks from lung and bleeding from damaged intercostal vessels are both potential complications. The principal contraindication is the presence of dense pleural adhesions.

### Transtacheal aspiration

Transtacheal aspiration is a technique designed to obtain secretions from the lower respiratory tract of patients with suspected pulmonary infection in such a way as to avoid contamination of the sample with oropharyngeal organisms [363]. Having been in vogue in the 1970s, its application has diminished more recently as it is an unpleasant procedure for the patient and one not without morbidity and even mortality [364]. Another reason for its diminished use is that the ideal patient is infrequently encountered in modern hospital practice. Such a patient has suspected pneumonia with consistent radiographic findings, has no past history of chronic or recurrent lower respiratory tract infection, has escaped prior treatment with an antibiotic, is well enough to be cooperative and is yet unable to raise sputum. It is accepted practice for clinicians to rely on the initial empirical use of antibiotics designed to cover the likely organisms while awaiting the result of sputum Gram stain and culture, despite the recognized deficiencies of these tests. Although past enthusiasts found wider applications for its use, transtacheal aspiration is now seldom carried out and most physicians would only consider it in patients with pneumonia of moderate severity in whom sputum was not produced, or when it failed to yield pathogens in a patient whose initial response to antibiotics had been poor.

### Technique

The various steps involved are explained to the patient, who is reassured and then placed in a supine position with two pillows under the shoulders and one under the head so that the chin can be lifted, hyperextending the neck somewhat. The neck is cleaned with iodine or an equivalent antiseptic and towels applied, full sterile procedure being followed throughout. The shallow flat depression of the cricothyroid membrane is palpated with the gloved forefinger between the thyroid and cricoid cartilages of the larynx. A little 1% lidocaine is applied to the skin in this

area but should probably not be introduced into the trachea as it may have bacteriostatic properties and also induces premature coughing. The patient is instructed not to swallow or cough and a 14-gauge needle containing an indwelling, thin (17 or 18 gauge), 20-cm polyethylene catheter (e.g. central venous pressure line) connected to a 20-mL syringe is introduced percutaneously into the trachea in the midline. Correct entry can be checked by withdrawing air into the syringe. The needle is angled in a caudal direction and the catheter quickly passed 8–12 cm into the trachea so that the tip is unlikely to be coughed upwards into the oropharynx. The needle is then quickly withdrawn from the skin in order to avoid the risk of laceration and the catheter remains *in situ*. Suction is then applied to the catheter in the hope of retrieving secretions. Should this not prove possible, 2–5 mL of non-bacteriostatic sterile saline may be injected through the cannula to induce coughing. Suction is again applied in this case and the retrieval of 0.5–2 mL of saline/secretions is considered a satisfactory specimen. Once such a sample has been obtained, the catheter is withdrawn and pressure applied manually to the puncture site for about 5 min, the patient being encouraged not to cough during this period. Air is ejected from the sampling syringe, which is then capped and taken directly to the laboratory where, following prior discussion with the microbiologist, Gram staining is carried out and aerobic and anaerobic cultures are set up, along with any other special staining or culture techniques that might be thought necessary according to the clinical circumstances. A small adhesive dressing is applied to the puncture site and the patient is asked to place a finger over this dressing and to press gently during coughing for the rest of the day.

## Yield

It is difficult to determine the accuracy of transtracheal aspiration as a technique for detecting the bacterial causes of lower respiratory tract infection because in order to do so comparison has to be made with another specimen source, the validity of which is beyond question. One study found that transtracheal aspiration yielded the same pathogen as that retrieved from blood culture in all of 23 patients with pneumonia accompanied by bacteraemia [365]; 488 patients in the same series were considered on clinical criteria to have bacterial pneumonia. The transtracheal aspirates were negative in 48 of these cases, giving a 'false-negative' result of 12.5%. It is of note that 44 of these negative isolates were obtained from patients who had received prior antibiotic treatment, leaving only four negatives in untreated patients; thus the false-negative rate in patients who had not received prior antibiotic treatment was only 1% [365].

Positive bacterial cultures may be obtained from the transtracheal aspirates of patients without clinical evi-

dence of pneumonia. Thus potential pathogens have been recovered from a combined group of 55 subjects (comprising normal volunteers and asthmatic subjects) in 13% of cases, presumably as a result of the colonization of the trachea and lower respiratory tract by bacteria [366]. Positive yields are also obtained in a high proportion of patients with chronic bronchitis or bronchiectasis [365,367].

## Complications

The complication rate of transtracheal aspiration in reported series is low, being approximately 0.5% for subcutaneous emphysema extending beyond the front of the neck, 0.2% for haemorrhage other than blood-streaking of the sputum, and 0.2% for paratracheal infection [368]. The physician whose experience with the technique is limited will realize that these low complication rates were recorded in units that developed a special interest in transtracheal aspiration and that this alone would be likely to enhance the safety of the test. As with other invasive procedures, fatalities have been recorded; such deaths have resulted from haemorrhage and from cardiac arrest following the aspiration of gastric contents, vomiting having been induced by vigorous coughing as a result of the procedure [364,369]. Unfortunately, serious complications are more likely to occur in those iller patients who may be most likely to benefit from any positive diagnostic information provided by the test.

Complications may be avoided by ensuring that the person carrying out the procedure is either well versed with the protocol or supervised by someone who is. The patient should be in a state in which cooperation is possible. Bleeding is avoided if the patient is not uraemic, the platelet count is not less than  $50 \times 10^9/\text{L}$  and the prothrombin and activated partial thromboplastin times are both normal. A low platelet count may be corrected by replacement, 6–12 packs being infused for a count of less than  $50 \times 10^9/\text{L}$ . Bleeding is also avoided by the application of gentle pressure by the operator to the cricothyroid membrane for about 5 min after the puncture. Blood-streaking in the sputum is to be expected and patients should be reassured about this. Serious hypoxia is guarded against by ensuring that the  $\text{PaO}_2$  is at least 9 kPa (about 70 mmHg) on supplemental oxygen prior to the procedure and by continuing to administer oxygen during the procedure while monitoring oxygen saturation [370]. Subcutaneous emphysema is seldom an inconvenience but may become alarming to the patient if it becomes extensive. It can be prevented if the patient applies gentle digital pressure to the puncture site during any coughing that might occur for the rest of the day. Infection of the puncture site is seldom a problem, probably because of the concurrent use of antibiotics for the chest infection, but has been reported [371,372].

# DRUGS IN LUNG DISEASE

DOUGLAS SEATON

This chapter is intended not as an exhaustive compendium of every drug that might conceivably be used in the management of respiratory illness but rather as a practical guide to certain groups of drugs worthy of consideration in this context. The first three sections cover antimicrobial agents used in bacterial, fungal and viral infection, including some drugs relevant to human immunodeficiency virus (HIV)-associated infections; further sections deal with bronchodilators and other drugs used in the treatment of airflow limitation, corticosteroids, respiratory stimulants and immunosuppressant/cytotoxic drugs. Antituberculous agents are discussed in Chapter 19. Readers who require a full account of individual agents are referred to standard texts on pharmacology and therapeutics and to the manufacturers' summaries of product characteristics.

## Antimicrobial agents for use against bacteria and bacteria-like organisms

### Penicillins

The penicillins are  $\beta$ -lactam antibiotics, so-called because they all contain a  $\beta$ -lactam ring in their molecular structure (Fig. 9.1). The different properties of individual members of the group (which also includes the cephalosporins, carbapenems and monobactams) mainly arise as a result of variations in the structure of their side-chain, one example of which has been the development of a subgroup of antistaphylococcal penicillins resistant to attack by  $\beta$ -lactamases.

#### *Mode of action*

All penicillins (in common with other  $\beta$ -lactam antibiotics) are bactericidal, attaching to so-called penicillin-binding proteins and interfering with bacterial cell wall synthesis, resulting in its disruption [1]. Many strains of bacteria, such as *Staphylococcus aureus*, produce  $\beta$ -lactamase enzymes that hydrolyse the penicillin molecule by disruption

of its  $\beta$ -lactam ring; many penicillins are susceptible to these  $\beta$ -lactamase producers, against which they are ineffective. Penicillins have no activity against organisms that lack a cell wall, such as *Mycoplasma pneumoniae*, and against other 'atypicals', such as *Chlamydia psittaci*, *Coxiella burnetii* and *Legionella* spp.

#### *Distribution and excretion*

Penicillins are widely distributed in body fluids. They cross the placenta but there is no evidence of adverse effects on the fetus. Most of these drugs are excreted in active form by the kidneys, a small fraction of broad-spectrum penicillins being excreted in bile. In the case of the ureidopenicillins this biliary excretion approaches 30%.

#### *Hypersensitivity reactions of penicillin and other $\beta$ -lactams*

The most serious adverse effects arise as a result of type I, immediate, anaphylactic, IgE-mediated hypersensitivity reactions, characterized by a combination of urticaria, angio-oedema, wheeze and hypotension and which may rarely result in collapse and death within minutes [2]. These reactions are more likely to occur following parenteral administration, but this may relate to dose rather than route [3]. Patients with no prior history of an allergic reaction may be affected, although a history of such a previous reaction increases the chance of a further attack four- to six-fold [4]. The incidence of these serious reactions has been estimated to be low, about 0.05%, and that of fatal ones much lower still, about 0.0002% [5,6]. Whereas 'immediate' reactions typically occur within a few minutes of taking an oral dose, other types of reaction may be more indolent, following different immunological pathways and sometimes taking 1–3 weeks to develop. Most penicillin reactions are in fact mild, taking the form of a late-onset (non-IgE-mediated) maculopapular erythematous rash in 2–3% of courses. Such rashes are more common following the use of semisynthetic penicillins, especially the aminopenicillins ampicillin or amoxicillin

Fig. 9.1 The  $\beta$ -lactam ring (a) and penicillin molecule (b). R indicates the site for side-chain substitutions.

(amoxycillin), occurring in approximately 5–10% of courses [3].

Unfortunately patients often have only vague recollections of past 'reactions' to antimicrobial agents, including penicillins. Many of these incidents may not have been allergic at all, despite which anxieties about their true nature often serve to block the further use of penicillins for the rest of the patient's life [7]. Sometimes this can be sorted out by an accurate history or reference to old records but doubts often remain. The place of formal testing to refute or confirm a suspected penicillin allergy, while an attractive concept, is unfortunately somewhat controversial [8]. There are various protein-bound derivatives of penicillins that, given the right circumstances, may cause allergic reactions following the administration of the drug in question. The most plentiful of these are formed by the opening of the  $\beta$ -lactam ring to form a penicilloyl derivative known as the 'major determinant'. However, penicillins may also undergo degradation by other mechanisms, producing a number of different protein-bound moieties also capable of exciting allergic reactions. These tend to be produced in smaller quantities and are therefore known as 'minor determinants'. To add to the complexity of the problem, the molecular side-chains of semisynthetic penicillins such as amoxycillin and ampicillin may also incite allergic reactions [3]. Skin-prick testing against major and minor determinants can be carried out with positive and negative controls by personnel properly trained in both the techniques and how to deal with reactions. A skin-test preparation containing the major (penicilloyl) determinant is commercially available but those containing minor determinants are not, so that one approach has been to prepare a solution of benzylpenicillin, at a dilution of 10 000 units/mL, as a less satisfactory surrogate for a minor determinant mixture [3]. If these tests are read as negative they may be repeated intradermally. Such intradermal testing has been reported to produce systemic reactions that are usually mild in about 1% of cases [9]. Using this approach, the positive test rate in patients previously thought to have possible allergy ranged between 7 and 35% for the most part, the positive test rate in control subjects being about 2% [3]. Many workers in this field take the view that it is safe to treat patients with  $\beta$ -lactams once they have undergone such studies with negative results and that when subsequent

reactions do occur in such patients they are almost invariably mild, no cases of anaphylaxis having been reported in the USA in such a situation [3]. On the other hand, a positive test indicates a significant chance of an immediate reaction if an antimicrobial of this class is used. A radioallergosorbent test (RAST) to detect IgE antibodies specific for penicillin has also been proposed as a guide in an outpatient setting [7], but again cannot be relied upon to predict outcome because the commercially available preparations are derived from the penicilloyl major determinant and do not test for the minor determinants [8], which may account for 10–25% of skin-test positive reactions [3].

Other serious systemic reactions are uncommon [10]. Non-IgE-type reactions include the following:

- 1 immune complex-mediated serum sickness reactions and drug fever;
- 2 blood dyscrasias, including reversible IgG- and/or IgM-mediated haemolytic anaemia that may result from the coating of red cells with antibody (positive Coombs test);
- 3 leucopenia, thrombocytopenia and reversible interstitial nephritis may be caused by similar mechanisms, all of these being conventionally treated with high doses of corticosteroids;
- 4 encephalopathy with convulsions may be a consequence of excessive dosage but can occur following normal doses in the presence of renal failure, especially in the elderly [11];
- 5 various rashes may occur, usually maculopapular erythematous reactions as already mentioned, but occasionally more serious reactions, such as exfoliative dermatitis or Stevens–Johnson syndrome, are described.

Avoidance of hypersensitivity reactions is best and most simply achieved by using an antibiotic of a different class whenever the suspicion of  $\beta$ -lactam allergy exists. Such avoidance should be complete when it is suspected from the history that a previous episode was an immediate IgE-mediated reaction or if the patient had one of the more serious skin reactions. Allergy testing may be considered in the outpatient setting but skin and RAST testing have no predictive value where the history is suggestive of a previous non-IgE-mediated allergic reaction. When the history of a previous reaction is less clear and if there is a pressing need, an alternative approach if a  $\beta$ -lactam is felt to be strongly indicated is to introduce one in hospital using gradual dose escalation under controlled conditions and with careful initial monitoring [3,8].

Cross-sensitivity occurs between different types of  $\beta$ -lactam antibiotic, indicating that these side-effects are often related to the basic double-ring structure of the  $\beta$ -lactam molecule. Cross-sensitivity between penicillins and cephalosporins is well known, although its frequency may have been overestimated in the past as a result of the contamination of early cephalosporin preparations with

small amounts of penicillin [3]. Such cross-reactions may also occur with the carbapenems (imipenem and possibly also meropenem), although current evidence indicates that the monobactam aztreonam, whose ring structure is monocyclic rather than bicyclic, may be safely administered to penicillin-allergic patients.

The management of hypersensitivity reactions should be by drug withdrawal. Mild cases may be controlled by this measure alone or by the oral administration of an antihistamine. More uncomfortable reactions may require systemic corticosteroid therapy. Anaphylaxis should be managed by lying the patient flat and by giving epinephrine (adrenaline) 0.5–1 mg i.m. (0.5–1 mL of epinephrine injection 1:1000), repeated every 15 min according to response. This may be supplemented by a slow (1-min) intravenous dose of an antihistamine such as chlorphenamine (chlorpheniramine) 10–20 mg. Systemic corticosteroids should also be commenced to prevent later deterioration. Wheeze may be treated with inhaled or parenteral bronchodilators according to severity.

### Narrow-spectrum short-acting penicillins

#### *Benzylpenicillin*

This so-called 'natural' penicillin is also known as penicillin G and was originally produced by the fungus *Penicillium notatum* and now by *P. chrysogenum*, a high-yield mutant mould. It has a relatively narrow spectrum and is short-acting.

#### *Susceptible organisms*

Important respiratory pathogens that are usually sensitive include *Streptococcus pneumoniae* and most anaerobes, including the clostridia, but with the notable exception of *Bacteroides fragilis* for which metronidazole may be added. Resistant *Strep. pneumoniae* have now been isolated in many parts of the world, particularly Spain, Iceland, some eastern European countries and North America. Resistance in this situation is not due to  $\beta$ -lactamase production but to changes in the penicillin-binding proteins of the pneumococcus so that these have a reduced affinity for the penicillin molecule [12]. Fortunately the resistance is relative (defined in terms of minimum inhibitory concentration, MIC) and there is evidence to suggest that in severe pneumococcal pneumonia the infection can still be overcome by therapeutic doses, with no increased mortality [13]. The problem of penicillin resistance is discussed in this context in Chapter 13. Other less common or rare organisms that are sensitive include microaerophilic streptococci such as *Strep. milleri*, *Strep. pyogenes*, *Pasteurella multocida*, *Actinomyces israelii*, *Corynebacterium diphtheriae* and *Bacillus anthracis*. Almost all strains of *Staph. aureus* are resistant as a result of their production of

Fig. 9.2 Structure of benzylpenicillin showing site of action of  $\beta$ -lactamase.

$\beta$ -lactamase (penicillinase), a group of enzymes that break open the  $\beta$ -lactam ring of the penicillin molecule (Fig. 9.2), thereby converting it to microbiologically inactive penicilloate. In a survey carried out as long ago as 1983, 80% of the hospital and community isolates of *Staph. aureus* were resistant to penicillin [14] and sensitive strains are now regarded by microbiologists as collector's items. Many other bacterial genera, species and strains produce  $\beta$ -lactamases, notably *Pseudomonas aeruginosa*, some *Proteus* spp., the anaerobe *Bacteroides fragilis*, most strains of *Moraxella catarrhalis* and increasing numbers of strains of *Haemophilus influenzae*.

#### *Administration and dose*

Benzylpenicillin is unstable in gastric acid and the drug should therefore be given either by intramuscular or intravenous injection. A dose of 600 mg (1 megaunit) i.m. or i.v. 6-hourly is sufficient for the majority of infections, although higher doses and prolonged administration may be required for more severe infections, such as anaerobic pneumonia and lung abscess. Peak blood levels are achieved within 15–30 min of intramuscular injection and as the urinary excretion of benzylpenicillin is brisk it is sometimes necessary to give very high doses in order to achieve the desired therapeutic effect. Such high dosing is made possible by the drug's relative lack of toxicity.

Benzylpenicillin was available as both a sodium and a potassium salt. Either one could be dispensed unless benzylpenicillin sodium or benzylpenicillin potassium was specifically prescribed. Only the sodium salt is now generally available in the UK, although both are obtainable in the USA. The choice is usually inconsequential but may be a consideration if the patient is in cardiac or renal failure, since 1 g of the former preparation contains 2.8 mmol of sodium and 1 g of the latter contains 2.7 mmol of potassium.

It is inadvisable to mix benzylpenicillin with other antibiotics in a syringe or in infusion fluid as incompatibilities may occur.

#### *Principal uses in respiratory medicine*

The main indication for benzylpenicillin in respiratory medicine is pneumococcal pneumonia and it may be used

as primary treatment in community-acquired pneumonia in young previously healthy patients (see Chapter 13). Its role in the management of empyema and lung abscess due to anaerobic infection is dealt with in Chapters 14 and 15.

### *Phenoxymethylpenicillin (penicillin V)*

Like benzylpenicillin, phenoxymethylpenicillin is a 'natural' penicillin produced when *P. notatum* and related moulds are fermented with phenoxyacetic acid. It is generally dispensed as the potassium salt in either tablet or oral suspension form, being relatively stable in gastric acid. Its antibacterial spectrum and distribution are rather similar to benzylpenicillin (see above), but it should not be used in serious infections because its absorption is unpredictable and incomplete [15]. Its principal respiratory use has been as a follow-up treatment in pneumococcal pneumonia once the infection is responding satisfactorily to initial treatment with parenteral benzylpenicillin, although commonly ampicillin or amoxicillin (which are less protein-bound) are now used in its place. It is also used to treat upper respiratory tract infections in children and in streptococcal sore throat. This drug may also be used long term at a dose of 250 mg daily as prophylaxis against pneumococcal infection in patients with asplenia or dysfunctional spleens [16] (see Chapter 13).

The adult dose is 250–500 mg every 4–6 h at least 30 min before food. The principal side-effects and their management are similar to those of benzylpenicillin. Tolerance is usually good but nausea and diarrhoea may occur. Colitis and hepatotoxicity have also been described but are uncommon [17,18].

### **Narrow-spectrum long-acting penicillins**

Certain poorly soluble salts of benzylpenicillin have been developed that have a prolonged effect when given as an intramuscular depot injection, resulting in the slow release of benzylpenicillin. Procaine benzylpenicillin (procaine penicillin; USA, penicillin G procaine) in a single large dose may inhibit susceptible bacteria for 24–36 h. Benzathine benzylpenicillin (benzathine penicillin; USA, penicillin G benzathine) is even less soluble and a single 900-mg dose may produce low concentrations of benzylpenicillin for 4 weeks [19]. It is no longer available in the UK.

The mode of action, antibacterial spectrum, excretion and side-effects are as for benzylpenicillin. In addition, procaine benzylpenicillin may produce side-effects as a result of its procaine component and should not be given to patients with a history of sensitivity to these types of local anaesthetics. Accidental intravenous administration may produce auditory disturbances, feelings of impending mortality, convulsions, tachycardia and hypertension.

None of these preparations have a role in the conventional treatment of severe acute respiratory infection. The longer-acting preparations have been used in situations of limited antibiotic availability or where compliance with oral therapy is unlikely to be fulfilled, but their use cannot be regarded as ideal.

### **Wider-spectrum penicillins: aminopenicillins**

Modifications to the basic penicillin structure by the substitution of various side-chains has resulted in the production of semisynthetic antimicrobial agents with a wider spectrum of activity than benzylpenicillin. The first of these was ampicillin, which has the particular attraction in respiratory medicine of being effective against *H. influenzae* as well as *Strep. pneumoniae*. The only other important member of this group is the ampicillin analogue amoxicillin, which is produced by the insertion of a hydroxyl group in the benzyl side-chain of ampicillin. Another analogue, ciclacillin (cyclacillin), although better absorbed than ampicillin, is also rapidly cleared and has inferior antibacterial activity [20] and is not considered further; neither are the ampicillin esters or 'prodrugs', talampicillin, pivampicillin and bacampicillin. These have no antibacterial activity of their own but are hydrolysed during their absorption to liberate ampicillin. They are more rapidly absorbed than ampicillin and may produce diarrhoea less frequently but tend to produce gastric upsets and probably have no clear advantage over ampicillin itself [21]. Ciclacillin, bacampicillin and talampicillin are no longer available in the UK. All the aminopenicillins are susceptible to  $\beta$ -lactamases.

### *Ampicillin and amoxicillin*

#### *Susceptible organisms*

These antibiotics are slightly less effective than benzylpenicillin against Gram-positive cocci, such as *Strep. pneumoniae*, but possess a broader spectrum of activity. As with benzylpenicillin, they are almost always ineffective against methicillin-sensitive *Staph. aureus* but their activity against some Gram-negative organisms such as *H. influenzae* is of clear importance in respiratory medicine. Although the majority of isolates of *H. influenzae* are still sensitive to the aminopenicillins, the incidence of resistant  $\beta$ -lactamase-producing strains of *H. influenzae* in the UK and elsewhere unfortunately continues to rise [22]. Resistance rates of 8–15% are not uncommon in this country, with much higher rates in Spain, so that it is advisable to know the sensitivity rates in one's own locality [23,24]. The susceptibility of other Gram-negative organisms is much less dependable. About 80% of *Moraxella catarrhalis* isolates are  $\beta$ -lactamase producers and are therefore usually resistant [25], as are most of the Enterobacteri-

aceae (including increasing numbers of *Escherichia coli* isolates) and other Gram-negative pathogens such as *Pseudomonas* spp.

#### *Administration and dose*

Both ampicillin and amoxicillin are acid-stable and may therefore be taken orally. The absorption of ampicillin is inhibited by food so it should not be taken after meals, whereas the absorption of amoxicillin is twice as good and is unaffected by food [26]. Thus an orally administered dose of 500 mg ampicillin produces peak serum levels at 2 h, the half-life in serum being 1 h, whereas the peak serum level for a similar dose of amoxicillin is twice as high. Although the half-lives of both preparations are comparable, detectable amounts of amoxicillin may be present for up to 8 h.

Distribution in body fluids is similar to that of the penicillin group as a whole, although there is good evidence to suggest that the sputum penetrance of amoxicillin is superior to that of ampicillin (see Chapter 28). As with other penicillins, the major route of excretion is in the urine and this may be blocked by probenecid. The dose of ampicillin or amoxicillin may require modification in severe renal failure [27].

The conventional oral dose is 250–500 mg, depending on severity, every 6 h for ampicillin and every 8 h for amoxicillin. The high oral dosage of amoxicillin (3 g twice daily) that is sometimes used in bronchiectasis has been discussed in Chapter 28. When parenteral therapy is required, 0.5–1 g 6-hourly by intravenous bolus injection is acceptable for either preparation.

#### *Adverse effects*

Hypersensitivity reactions may occur with ampicillin and amoxicillin as for any member of the penicillin group and the principles of management are as described above. The range of further side-effects is similar for both antibiotics. Cutaneous rashes are much more frequent than with narrow-spectrum penicillins, occurring in about 7% of patients [3,28], and are the most common adverse effect. As these rashes are usually delayed and are macular or maculopapular rather than urticarial, they may be due to impurities and not an indication of true allergy to the penicillin nucleus or side-chains themselves [29,30]. Subsequent treatment with another penicillin or even with the same antibiotic may be undertaken without further trouble being inevitable, provided that a proper indication exists. However, an urticarial rash invariably implies true penicillin allergy and further dosage could be dangerous (see p. 193). Amoxicillin and ampicillin are particularly likely to cause rashes in patients with infectious mononucleosis, cytomegalovirus infection and acute lymphocytic leukaemia [31].

Oral candidiasis is common, as is the case with many broad-spectrum antibiotics; nausea, vomiting and diarrhoea may occur particularly with higher dosages. Pseudomembranous colitis caused by *Clostridium difficile* has been described but is unusual [32,33]; it is often self-limiting and need not necessarily require treatment with metronidazole or vancomycin.

#### *Principal uses in respiratory medicine*

The principal respiratory indications for these drugs are the management of infective exacerbations of chronic bronchitis, for which they remain a standard first-line agent (see Chapter 23), community-acquired pneumonia (see Chapter 13), bronchiectasis (see Chapter 28) and sinusitis (see Chapter 12).

#### *Amoxicillin–clavulanate (co-amoxiclav)*

Clavulanic acid is a naturally occurring penicillin compound found in cultures of *Streptomyces clavuligerus* [34]. It has negligible antibacterial activity of its own but is a  $\beta$ -lactamase inhibitor, binding to and irreversibly inhibiting many mainly plasmid-encoded  $\beta$ -lactamases produced by a variety of Gram-negative and Gram-positive bacteria. The potassium salt of clavulanic acid has therefore been combined in proprietary form with amoxicillin in order to extend the spectrum of the latter against certain  $\beta$ -lactamase-producing organisms that would ordinarily hydrolyse the  $\beta$ -lactam ring of the penicillin molecule to produce microbiologically inactive penicilloate.

Other examples of  $\beta$ -lactam/ $\beta$ -lactamase combinations are ampicillin–sulbactam (sultamicillin), which is available in the USA and other countries but not in the UK, and two extended-spectrum penicillins, ticarcillin–clavulanic acid and piperacillin–tazobactam (see p. 199).

#### *Susceptible organisms*

Co-amoxiclav may possess activity against amoxicillin-resistant strains of *H. influenzae*, *Moraxella catarrhalis*, *Staph. aureus*, *Klebsiella aerogenes* and *E. coli*. Unfortunately, it has no activity against the chromosomal  $\beta$ -lactamases produced by *Ps. aeruginosa*, *Enterobacter* and *Serratia* species, which are therefore resistant to it. This drug is likely to be effective in respiratory tract infections caused by organisms known to be resistant to amoxicillin alone, such as certain strains of *H. influenzae* and *Moraxella catarrhalis* [35]. In clinical practice, it may be used empirically as a second-line agent in patients with community-acquired exacerbations of chronic obstructive pulmonary disease (COPD) who have not responded to a first-line antimicrobial such as amoxicillin alone, or in patients who are iller and in whom broader cover from the onset seems more prudent. The combination also has useful activity

against anaerobes, including *Bacteroides fragilis*, although clinical trials are lacking in this difficult area (see Chapter 13). The drug is also useful in the upper respiratory tract for treating sinusitis. Data are poor for its use in serious staphylococcal infections, for which good alternatives already exist; more potent drug combinations also exist for treating serious respiratory infections thought to be caused by the Enterobacteriaceae, *E. coli* and *Klebsiella aerogenes* (see Chapter 13).

#### Administration and dose

The dose, expressed as amoxicillin, is 250–500 mg 8-hourly; at each dose level, the accompanying dose of clavulanate is the same (125 mg). On a point of economics, it is currently cheaper for an institution to dispense a lower-dose combination (250/125 mg) and an additional 250-mg dose of amoxicillin than to use the more expensive 500/125 mg preparation. For severe infection co-amoxiclav may be given parenterally (not available in USA) by infusion or slow intravenous injection of 1.2 g (1 g amoxicillin, 200 mg clavulanic acid) every 6–8 h.

#### Adverse effects

Side-effects are similar to those encountered with amoxicillin and the same precautions have to be applied to its use in patients with serious renal insufficiency. There have been some reports of cholestatic jaundice occurring in association with co-amoxiclav and it is suspected that this may be due to the clavulanate constituent [36]. This problem may be more relevant in elderly patients who receive prolonged courses.

#### Antistaphylococcal penicillins: methicillin, cloxacillin, flucloxacillin, oxacillin, dicloxacillin and nafcillin

Methicillin was the first of this group of semisynthetic penicillins, which contain acyl side-chain modifications that protect their molecular structure from hydrolysis by

staphylococcal  $\beta$ -lactamases. This structural modification gives these antibiotics bactericidal activity against *Staph. aureus* but renders them ineffective against Gram-negative bacteria, including *H. influenzae*, and Gram-positive cocci, including *Strep. pneumoniae*, against which benzylpenicillin is up to 20 times more effective [37]; thus the only indication for their use is the treatment of staphylococcal infection. The increasing numbers of isolates of methicillin-resistant *Staph. aureus* (MRSA) have gained their biological advantage not as a result of  $\beta$ -lactamase production but by acquisition of a low-affinity penicillin-binding protein, rendering them resistant to the antistaphylococcal penicillins as a group.

Three antistaphylococcal penicillins used to be available in the UK: methicillin, cloxacillin and flucloxacillin. There have been concerns that penicillin-related interstitial nephritis is more common with methicillin and this antibiotic is no longer marketed in the UK. Oxacillin, dicloxacillin and nafcillin are available in the USA but not in the UK; flucloxacillin is unavailable in the USA. Their properties are summarized in Table 9.1.

Methicillin is acid-labile and can therefore only be given parenterally. Its use is therefore limited to the treatment of severe penicillin-resistant staphylococcal infections. Methicillin is rapidly excreted by the kidneys, like benzylpenicillin, and some dosage reduction may need to be made in severe renal failure [27]. This is not the case with other members of the group such as flucloxacillin, which although excreted by the kidneys also undergoes significant metabolism in the liver. The serum concentration and half-life of all members of the group may be increased by probenecid.

Parenteral administration of this group of drugs is generally preferable in systemic staphylococcal infection and mandatory in bacteraemia (Table 9.2). Where oral administration is contemplated then flucloxacillin (UK) or dicloxacillin (USA) are the best absorbed. Cloxacillin, nafcillin and particularly oxacillin are all less well absorbed by comparison with flucloxacillin and dicloxacillin. Absorption of all five drugs is further reduced by food in

**Table 9.1** Properties of antistaphylococcal penicillins. (After Wise [37].)

the gut and they should preferably be taken 1 h before meals.

Flucloxacillin is commonly used in the UK as it has a similar antistaphylococcal activity to cloxacillin while achieving better absorption and higher blood levels [38,39]. Cholestatic jaundice has occasionally been reported with the use of flucloxacillin and hepatotoxic reactions have also occurred with other members of this group [39]. This problem appears to be more likely in older patients who receive the drug for longer than 2 weeks [40].

#### Extended-spectrum (antipseudomonal) penicillins: carboxypenicillins and ureidopenicillins

A number of semisynthetic penicillins have been developed for their bactericidal activity against *Ps. aeruginosa*, an organism resistant to all other penicillins so far described. Two of the antipseudomonal penicillins belong to the carboxypenicillin group: ticarcillin and carbenicillin [41]. Three remaining antibiotics belong to the ureidopenicillin group: azlocillin, piperacillin and mezlocillin [42]. Although all have therapeutic antipseudomonal activity, dose for dose piperacillin is the most potent agent, followed by azlocillin. Mezlocillin and ticarcillin are of approximately equal antipseudomonal potency and carbenicillin is the least effective, so that higher doses are required with an increased likelihood of side-effects. Carbenicillin also carries a high sodium load and may, as a result of a high, non-reabsorbable renal anion load produce hypokalaemia; it is no longer commercially available in the UK and neither is mezlocillin. Piperacillin is described below as an example.

#### Piperacillin

##### Susceptible organisms and main indications

Whereas azlocillin is 8–11 times more potent than carbenicillin as an antipseudomonal agent, piperacillin possesses even greater *in vitro* potency [42,43] and has been shown to

be effective in serious bacterial infections. The only clear indication for its use is the knowledge or suspicion that such serious infection is due to *Pseudomonas* spp. or other Gram-negative enteric bacilli, such as *E. coli*, *Klebsiella* and *Proteus* spp. These types of organisms are often responsible for severe hospital-acquired pneumonia (see Chapter 13). It is common practice when treating a severe pseudomonal or other Gram-negative enteric bacillary infection to use an aminoglycoside such as gentamicin as well as an antipseudomonal penicillin, as resistance to the penicillin may emerge if it is used singly [44], whereas together they act synergistically. It is worth noting that piperacillin's spectrum of activity covers other organisms and that it is as effective as ampicillin against Gram-positive cocci [43] and is also active against *H. influenzae*. It is susceptible to  $\beta$ -lactamases produced by *Staph. aureus*. The extended-spectrum penicillins also have good activity against anaerobic mouth flora, a property that may be useful for mixed pneumonic infections in which aspiration may have occurred. Many of these properties are shared by azlocillin and mezlocillin and to a lesser extent by ticarcillin and carbenicillin.

##### Administration and dose

Piperacillin, in common with all other antipseudomonal penicillins, has to be given intravenously so that adequate blood levels can be achieved. The drug is moderately protein-bound (20–40%) and its distribution is similar to that of other penicillins. It is rapidly excreted by the kidneys and has a plasma half-life of about 1 h. This is prolonged in renal insufficiency or if probenecid is used concurrently. These properties are shared to varying degrees by the other extended-spectrum penicillins. The side-effects are those of any penicillin (see pp. 193–195). Piperacillin has a much lower sodium content (about 1.7 mEq/g) than carbenicillin, reducing the risk of congestive heart failure in susceptible individuals. The risk of hypokalaemia due to a high anion load on the distal tubules is also diminished.

The usual dose is 12–18 g infused intravenously in four divided doses daily, each over 20–40 min. The extended-spectrum penicillins should never be mixed with an aminoglycoside in the same infusion or syringe as the penicillin binds chemically to the other antibiotic [45].

##### Piperacillin–tazobactam and ticarcillin–clavulanate

Piperacillin has been combined with tazobactam, a  $\beta$ -lactamase inhibitor like both clavulanic acid and sulbactam, and is now available as a parenteral preparation piperacillin–tazobactam (Tazocin) [46] for use with an aminoglycoside in serious infections, including hospital-acquired pneumonia and those associated with neutropenia. There appears to be no enhancement of its

antipseudomonal activity but the combination has activity against *Staph. aureus* and its activity against some Gram-negative enteric bacilli and *H. influenzae* is enhanced. The usual dose is 4.5 g (piperacillin 4.0 g, tazobactam 0.5 g) every 8 h.

The bacterial spectrum covered by piperacillin-tazobactam is similar to that achieved by another combination of extended-spectrum penicillin and  $\beta$ -lactamase inhibitor, ticarcillin-clavulanate (Timentin) [47], which may also be combined with an aminoglycoside to treat the same range of serious infections. The usual dose is 3.2 g (ticarcillin 3 g, clavulanic acid 200 mg) every 6–8 h.

Temocillin is a more recent parenteral penicillin that has increased resistance to the  $\beta$ -lactamases produced by many Gram-negative organisms, including *H. influenzae* and *Moraxella catarrhalis*. However, it must be stressed that it has no useful activity against *Ps. aeruginosa* and little or no activity against staphylococci, streptococci and anaerobes [48]. These are clearly major drawbacks in the treatment of serious lower respiratory tract infection, in which initial treatment is usually empirical and designed to cover a wide spectrum of core organisms (see Chapter 13). It therefore has no obvious role in respiratory medicine.

### Cephalosporins

This seemingly ever-enlarging group of antibiotics has some general points in common with the penicillins. Cephalosporins were also developed from the product of a mould (originally known as *Cephalosporium acremonium*). Like penicillins, cephalosporins are bactericidal and also have their effect by attaching to penicillin-binding proteins on the bacterial cell wall, which is then disrupted. Their chemical nucleus is somewhat similar to that of penicillin, including the presence of a  $\beta$ -lactam ring (Fig. 9.3). This ring, essential for the stability of the cephalosporin molecule, may be attacked by  $\beta$ -lactamases produced by a range of organisms, both Gram-positive, such as *Staph. aureus*, and Gram-negative, such as the Enterobacteriaceae. Just as different penicillins have been synthesized by side-arm substitutions so have the cephalosporins, although in the latter case there are not one but two substitution points, one of which (R' in the C-3

Fig. 9.3 Structure of the cephalosporin nucleus showing  $\beta$ -lactam bond. R and R' represent substitution points.

position) affects pharmacokinetics and the other (R) antibacterial activity (Fig. 9.3). Innumerable modifications have been made to the molecular structure of these 'designer drugs', so that their individual antibacterial properties result from varying degrees of  $\beta$ -lactamase stability, cell membrane penetrance and penicillin-binding protein affinity. With some exceptions they are excreted unchanged in the urine (at a rate that may be slowed by probenecid) and dosage modification may be required in renal insufficiency.

### Adverse effects

As a group, cephalosporin toxicity is low, a further point of similarity with the penicillins. Anaphylactic reactions are very rare but some subjects who are allergic to penicillins also show hypersensitivity to cephalosporins [3]; thus substitution of the second class of drug for the first may not be entirely hazard-free, although the risk is low [49]. Allergy to  $\beta$ -lactams in general has been discussed in the section on penicillin. Rashes may occur as with penicillins [50]. Nausea, vomiting and diarrhoea may also occur, sometimes with *Clostridium difficile*-associated colitis, as with other broad-spectrum antibiotics, particularly penicillins and clindamycin [51,52]. Diarrhoea is probably more likely in those preparations that are poorly absorbed or that are excreted to a significant degree in bile. Minor disturbances of liver function may be observed [50].

The potential for nephrotoxicity is low but does exist [53], particularly with one of the earliest members of the group, cefaloridine (cephaloridine), which has been withdrawn from general availability in the UK and USA. Although cefalotin (cephalothin) has been implicated in acute tubular necrosis, particularly in the elderly, it is still obtainable in the USA. In renal insufficiency, dose modification is generally needed, although with cefotaxime, which is metabolized, this is only necessary in severe impairment (glomerular filtration rate <10 mL/min). As with the penicillins, interstitial nephritis may rarely occur as an allergic reaction to cephalosporins.

High or prolonged dosage of some cephalosporins has been associated with a haemorrhagic tendency [54,55] due to interference with vitamin K-dependent clotting factors or platelet function but this is unusual, particularly with the cephalosporins currently available in the UK (Table 9.3). It is associated only with those drugs that have an N-methylthiotetrazole (MTT) substitution at the C-3 position indicated by R' (Fig. 9.3). Included among these is cefamandole. Patients may occasionally develop positive direct antiglobulin (Coombs) reactions but haemolytic anaemia is rare as is neutropenia [56,57].

A disulfiram reaction to alcohol may also occur with cefamandole and with other cephalosporins with the MTT

group at R' on the cephalosporin ring structure (Table 9.3). These MTT reactions were particularly noted with latamoxef (moxalactam, USA), this drug having been withdrawn from general availability.

**Classification and spectrum of activity**

There are currently 17 cephalosporins listed in the *British National Formulary* [58], allowing for one cephamycin antibiotic (cefoxitin) sufficiently closely related chemically to permit its inclusion in the group (Table 9.3). Only one of this number is currently unavailable in the USA (cefodizime), and the USP lists seven that are unavailable in the UK: cephapirin, cefonicid, cefprozil, loracarbef (a carbacephem), cefotetan, cefmetazole, cefoperazone and cefepime. Current European Union legislation is attempting to standardize the spelling of many drugs, including that of the cephalosporins so that they all begin with the letters 'cef'. The remaining parts of the generic names are seemingly designed to test the physician's memory, as indeed are the various merits and demerits of this profuse group of drugs.

One well-established, if somewhat arbitrary, method of cephalosporin classification is according to the antimicro-

bial spectrum, each antibiotic, whether oral or parenteral, being assigned to one of three 'generations' as befits its antibacterial activity [59] (Table 9.3). As with the penicillins, the cephalosporins are all ineffective in the treatment of respiratory infection due to organisms causing so-called 'atypical pneumonia', such as *Mycoplasma pneumoniae*, *Chlamydia pneumoniae* and *C. psittaci*, *Coxiella burnetii* and *Legionella* spp. Cephalosporins in general are inactive against enterococci, although these cause respiratory infection extremely rarely [60]. Only certain members of the third generation are active against *Ps. aeruginosa*.

**First-generation cephalosporins**

This group includes cefradine (cephradine) (parenteral/oral), cefalexin (cephalexin) (oral), cefazolin (cephazolin) (parenteral) and cefadroxil (oral). The first-generation cephalosporins have a relatively narrow spectrum, with excellent activity on Gram-positive cocci. They therefore tend to be effective against the pneumococcus and methicillin-sensitive *Staph. aureus*. They are active against many anaerobes but (as with benzylpenicillin) *Bacteroides fragilis* is resistant. Their drawback for many community-

acquired lower respiratory tract infections in patients with pre-existing lung disease is a relatively poor level of activity against *H. influenzae* and *Moraxella catarrhalis*. They have no activity against *Ps. aeruginosa* and are unreliable for treating infections where other aerobic Gram-negative enteric bacilli might be anticipated, such as in hospital-acquired pneumonia (see Chapter 13).

Individual drug points:

- 1 Cefazolin: 8-hourly dosing, whereas cefradine requires 6-hourly.
- 2 Cefalexin, cefradine and cefadroxil all well absorbed.
- 3 Cefadroxil: twice-daily dosing, although its half-life is not long.

### Second-generation cephalosporins

This group includes cefaclor (oral), cefuroxime (parenteral/oral as ester), cefamandole (cephamandole) (parenteral) and cefoxitin (parenteral). Cefoxitin is actually a cephamycin produced by a species of *Streptomyces* but is chemically similar to the cephalosporins and is therefore included in the group. This group has more variable activity than the first-generation drugs against Gram-positive cocci but improved activity against Gram-negative bacteria (including *H. influenzae* and *Moraxella catarrhalis*), with the notable exception of *Ps. aeruginosa*, against which all members of this group are ineffective.

Individual drug points:

- 1 Cefuroxime is more active than first-generation drugs against the pneumococcus but less so against *Staph. aureus*. It is active against *H. influenzae*, *Moraxella catarrhalis* and other Gram-negative bacilli. The oral prodrug (cefuroxime axetil) [61] is taken twice daily but, in common with comparable agents, its absorption characteristics result in diarrhoea in up to 4% of recipients, with occasional *Clostridium difficile* infection.
- 2 Cefamandole is active against Gram-positive cocci but is less reliable than cefuroxime against Gram-negative bacilli.
- 3 Cefaclor has problems with resistant strains of  $\beta$ -lactamase-producing *H. influenzae* and *Moraxella catarrhalis*.
- 4 Cefoxitin has better activity against *Bacteroides fragilis* and some Gram-negative bacilli but this is offset by reduced activity against both Gram-positive cocci and *H. influenzae* compared with other group members.

### Third-generation cephalosporins

This group includes ceftazidime (parenteral), cefotaxime (parenteral), ceftriaxone (parenteral), ceftipime (parenteral), cefpodoxime (oral), ceftibuten (oral), cefixime (oral) and ceftizoxime (parenteral and no longer generally available in the UK). This extended-spectrum group is

more diverse, with increased stability against  $\beta$ -lactamases than drugs of the other two generations [37]. Third-generation cephalosporins are noted for a high level of activity against Gram-negative enteric bacilli, e.g. *Enterobacter* spp., *E. coli*, *Serratia marcescens*, *Klebsiella* and *Proteus* spp.; some members are active against *Ps. aeruginosa* (Table 9.3). Coverage may therefore extend to those organisms that frequently cause serious hospital-acquired and intensive care unit-linked pneumonia. These antipseudomonal drugs are also effective against *H. influenzae* and *Moraxella catarrhalis* and have a good degree of activity against the pneumococcus, but are weaker than the first-generation cephalosporins against methicillin-sensitive *Staph. aureus*. Many strains of *Bacteroides fragilis* are resistant. The oral third-generation cephalosporins tend to be less active against Gram-positive organisms as a trade-off for their increased Gram-negative activity.

Individual drug points:

- 1 Ceftazidime and ceftipime are also antipseudomonal; of these ceftipime is more effective than ceftazidime against both streptococci and staphylococci but is not such a powerful antipseudomonal.
- 2 Cefotaxime, ceftriaxone and ceftizoxime all have similar antibacterial activity. However, ceftriaxone, being highly protein-bound and with a long half-life, may be given by once-daily injection, a factor of potential economic importance. It is excreted in both urine and bile so that its dose needs modifying only if renal and hepatic insufficiency coexist; it also has a propensity to form a biliary precipitate ('biliary sludge') and symptoms of cholecystitis if used at prolonged or high dose [62].
- 3 Ceftizoxime is excreted unchanged in the urine so dose adjustment is needed in renal insufficiency and it is no longer generally available in the UK.
- 4 Cefixime and ceftibuten are oral agents, sharing the general characteristics of the group but with pharmacokinetics permitting once-daily dosage. Only 20% of cefixime is recoverable in the urine [63], a fact that reflects relatively poor absorption and that might increase the likelihood of diarrhoea [64]. Ceftibuten has borderline *in vitro* activity against *Strep. pneumoniae* but may compensate for this clinically as a result of good pharmacokinetics [65].
- 5 Cefpodoxime proxetil is an oral prodrug that is esterified to release cefpodoxime. It requires twice-daily dosage and is highly active against *H. influenzae* and *Moraxella catarrhalis* [65]. It is effective against *Strep. pneumoniae* and has moderate activity against *Staph. aureus*, whereas cefixime and ceftibuten do not.

### Summary of principal uses of cephalosporins in respiratory medicine

Although oral cephalosporins are seldom the drugs of first choice in respiratory infections, they have nevertheless

been very widely prescribed in North America and in out-of-hospital general practice in the UK, a tendency that may be reinforced by the arrival of a number of newer oral third-generation members [65]. As a group, they are relatively expensive and it is debatable whether the benefits that these oral agents have conferred are commensurate with their cost.

Community-acquired pneumonia is most commonly caused by *Strep. pneumoniae*. Although cephalosporins of any generation may be effective against this organism, they are less so than benzylpenicillin and have not been shown to be better in clinical practice (as opposed to *in vitro* testing) than amoxicillin or ampicillin, both of which are cheaper. Cefuroxime may be used in a patient ill enough to require parenteral treatment for pneumonia (see Chapter 13), particularly when there is concern about the possibility of resistant *H. influenzae* or *Moraxella catarrhalis*, such as in older patients or those with chronic lung disease. Although cephalosporins may be variably active against methicillin-sensitive *Staph. aureus* infection, an antistaphylococcal penicillin is the drug of first choice in this situation [66]. Third-generation cephalosporins need not be used routinely for community-acquired pneumonia, for which empirical treatment on the basis of probability with more narrowly targeted antimicrobials is more appropriate (see Chapter 13).

There is no convincing evidence to indicate that cephalosporins have a major role in the management of acute purulent exacerbations of COPD. The first-generation oral cephalosporins, cefradine, cefalexin and cefadroxil are unsuitable oral treatment for exacerbations of chronic bronchitis because although active against *Strep. pneumoniae* they are inactive against *H. influenzae* and *Moraxella catarrhalis* [67,68]. Resistance to second-generation cefaclor may also occur with some strains of *H. influenzae* and with *Moraxella catarrhalis*. Evidence is lacking to suggest that cefaclor is clinically any more effective than ampicillin or amoxicillin in this situation. When an exacerbation is associated with sputum isolates of amoxicillin-resistant *H. influenzae* and if this drug is failing, then the second-generation oral cephalosporin cefuroxime axetil may be indicated, alternatives being co-amoxiclav, one of the newer macrolides such as clarithromycin, or a fluoroquinolone such as ciprofloxacin. The third-generation oral cephalosporins generally lose their Gram-positive efficacy as a price for improved Gram-negative cover and there are no reliable trials to demonstrate that they are clinically superior to earlier compounds [69]. They are also expensive and their only clear advantage over older agents is reduced dose frequency.

The use of the antipseudomonal parenteral third-generation cephalosporins should be restricted to situations where infection with *Ps. aeruginosa* is suspected or confirmed [70]. These drugs lend themselves to the treat-

ment of severe hospital-acquired pneumonia (see Chapter 13), in which Gram-negative bacteraemia is often suspected, and also exacerbations of lower respiratory tract infection in which *Ps. aeruginosa* is known to be a colonist, e.g. in cystic fibrosis and bronchiectasis. The combination of an appropriate third-generation cephalosporin such as ceftazidime with an aminoglycoside gives a broad degree of cover for pathogens such as *Ps. aeruginosa*, *Klebsiella aerogenes* and other Enterobacteriaceae [71]. There is probably little to choose between such a regimen and those containing an extended-spectrum antipseudomonal penicillin (see p. 199) and an aminoglycoside or a carbapenem such as imipenem/cilastin or meropenem (see p. 204) with an aminoglycoside. Both regimens might need the support of an antistaphylococcal penicillin according to clinical circumstances. Needless to say, reasonable efforts should be made to determine the nature of the causative organism and treatment may be modified in the light of laboratory findings.

Those third-generation members with no antipseudomonal activity may have a place in the treatment of somewhat less severe ward-based cases of hospital-acquired pneumonia in which Gram-negative infections are thought to be likely, cefotaxime or ceftriaxone being reasonable choices in this situation (see Chapter 13).

One of the ever-present dangers of the overuse of third-generation cephalosporins is the induction of increasing numbers of chromosomally mediated extended-spectrum  $\beta$ -lactamases by enteric Gram-negative bacilli [12]. The genes encoding these  $\beta$ -lactamases may be disseminated among other Gram-negative bacilli, resulting in a steadily increasing pool of organisms that are resistant to many antimicrobial agents [12].

For dosages of the cephalosporins the reader is referred to the *British National Formulary* or to product data sheets [58].

### Other $\beta$ -lactam antibiotics

Apart from the penicillins and cephalosporins, there are two other classes of  $\beta$ -lactam antibiotic, the monobactams and carbapenems.

#### Monobactams

##### *Aztreonam*

Aztreonam is a parenteral antibiotic that is the only currently available member of the monobactam group, so-called because the  $\beta$ -lactam ring is single rather than bicyclic as is the case with the other  $\beta$ -lactam antibiotics. It has a narrow spectrum, being active against Gram-negative bacteria including most Enterobacteriaceae, *Ps. aeruginosa* and *H. influenzae* but having no significant activity against Gram-positive organisms or anaerobes.

This is because it attaches selectively only to those penicillin-binding proteins found on Gram-negative aerobic organisms. Although it has been used in patients with serious lower respiratory tract infections, it should not be used alone on an empirical basis if there is a possibility of a mixed infection with involvement of aerobic Gram-positive or anaerobic organisms. It can apparently be used with impunity in patients who are hypersensitive to penicillins and other  $\beta$ -lactams (see p. 193) [72].

## Carbapenems

### *Imipenem–cilastatin and meropenem*

Imipenem was the first member of the carbapenem class of  $\beta$ -lactams. It is given intravenously by infusion in combination with cilastatin, a renal dipeptidase inhibitor that prevents renal metabolism, increasing urinary excretion of the active drug and inhibiting its transformation into a nephrotoxic metabolite. This drug has a very broad spectrum of activity, encompassing most Gram-negative and Gram-positive aerobic and anaerobic bacteria including most species that produce  $\beta$ -lactamases [73,74]. It is ineffective against MRSA.

Meropenem is the second member of the carbapenem class of  $\beta$ -lactams and has a spectrum of activity very similar to imipenem. It does not require combination with cilastatin and may be given by intravenous bolus injection rather than infusion.

### *Adverse effects*

Imipenem–cilastatin may cause phlebitis at the injection site. Other adverse effects are similar to those described under penicillin. As with any  $\beta$ -lactam, excessive dosage may produce seizures, and dose modification in the presence of renal impairment (glomerular filtration rate  $<50$  mL/min) is advisable. Meropenem appears to be less liable to cause seizures.

### *Principal uses in respiratory medicine*

Both these carbapenems may be used in patients with serious hospital-acquired pneumonias and in febrile neutropenic patients, who are likely to be bacteraemic. Although they may be used as monotherapy, particularly in febrile neutropenic patients [74], resistant strains of *Ps. aeruginosa* may emerge, as with other single-agent treatments; thus these drugs are often combined with an aminoglycoside, particularly when used to treat more chronic sepsis such as in cystic fibrosis. Both drugs are probably as effective as the more conventional extended-spectrum penicillins or third-generation anti-

pseudomonal cephalosporin/aminoglycoside combinations [75]. Although similarly priced, they are both costly and should be considered when problems with resistance to less expensive regimens are encountered.

## Macrolides

This group includes erythromycin, clarithromycin, azithromycin, roxithromycin, dirithromycin and others.

### *Erythromycin*

Erythromycin was originally obtained from the mould *Streptomyces erythreus* and was for many years the only antibiotic of any clinical importance belonging to the macrolide group.

### *Mode of action*

Erythromycin is primarily bacteriostatic, although in high concentration it may be bactericidal to small numbers of rapidly dividing bacteria [76]. It has its effect by reversibly binding to bacterial ribosomes, with the result that RNA-dependent protein synthesis is inhibited.

### *Spectrum of activity against respiratory pathogens*

The range of activity of erythromycin overlaps the spectrum of some penicillins so that it may be substituted for penicillin, ampicillin or amoxicillin in patients who are thought to be allergic to these drugs. Although it usually has good *in vitro* activity against *Strep. pneumoniae*, there have been increasing concerns about the emergence of pneumococci resistant to erythromycin [77–79]. Such patterns of drug resistance may be geographically based, depending on the degree of local use [80]. The activity of erythromycin and other macrolides is unaffected by the presence of  $\beta$ -lactamases. There are theoretical concerns about the effectiveness of macrolides, which are predominantly concentrated intracellularly, on bacteraemic pneumococcal infection [81]. Erythromycin usually remains active against *Strep. pyogenes* (syn.  $\beta$ -haemolytic or group A streptococcus) but is less so against methicillin-sensitive *Staph. aureus* and resistant forms of this organism may emerge during treatment [82,83]. The emergence of resistance to erythromycin during treatment may occur via various mechanisms and is more likely to develop during a prolonged course of treatment (e.g. for endocarditis) than with a standard course, such as is used in respiratory disease [84]. Erythromycin is the drug of choice in the treatment of *Mycoplasma pneumoniae*, *Legionella pneumophila* and *Chlamydia* spp. infections. It may be effective in treating infection caused by *Moraxella catarrhalis* and *Coxiella burnetii* but has only moderate activity against

anaerobic infection. Many strains of *H. influenzae* are now resistant [85]. It has no significant activity against the Gram-negative Enterobacteriaceae, including *E. coli*, *Proteus*, *Klebsiella*, *Serratia*, *Citrobacter* and *Yersinia* spp. Erythromycin has been used in pertussis prophylaxis and treatment before it reaches the paroxysmal stage of whooping cough (see Chapter 12) and is also effective against *Corynebacterium diphtheriae*.

#### *Administration, distribution and excretion*

Erythromycin base is inactivated by gastric acid and is therefore available in enteric-coated formulations as a stearate salt or in esterified form in order to allow its passage through the stomach intact. Erythromycin stearate dissociates in the duodenum, being hydrolysed and absorbed as erythromycin base in the upper small bowel. Conversely, erythromycin estolate is absorbed from the small bowel intact before undergoing hydrolysis to release the base. An ethylsuccinate ester also exists that may be taken in liquid form. Oral absorption is usually adequate [86] but varies between individuals [87], and in serious infection parenteral treatment is recommended, at least initially. The intramuscular route is painful and therefore avoided.

The half-life of erythromycin is approximately 1.5h, during which time it diffuses well into most tissues and into sputum [86,88]. It crosses the placenta but can be used safely in pregnancy. Less than 15% of a given dose is excreted unchanged in the urine and dosage reduction is not therefore usually necessary in renal failure [89]. Some of the drug is concentrated in the liver, some excreted in bile and the remainder degraded.

#### *Dosage*

The oral dose of erythromycin is 250–500 mg every 6 h; the intravenous dose is 0.5–1 g every 6 h [77]. Pharmacokinetic data suggest that this regimen is more appropriate than twice-daily dosing.

#### *Adverse effects*

Erythromycin is one of the safest antibiotics available. Oral or parenteral administration may produce dose-related nausea and occasional epigastric discomfort, vomiting or diarrhoea. These effects may occur in 20–30% of patients taking erythromycin 500 mg four times daily and are less frequent with the newer, more expensive macrolides [90]. Intravenous use may be bedevilled by local thrombophlebitis, which can be reduced or avoided by diluting the drug in 250 mL normal saline and infusing it over 1 h rather than by giving it as bolus injections [91].

Cholestatic jaundice is the most important side-effect. It is non-fatal and reversible within days or weeks of drug withdrawal. It occurs infrequently but when it does usually follows the use of erythromycin in adults for periods exceeding 10 days [92,93]. The risk of jaundice is said to be increased in pregnancy, in which condition the estolate should be avoided [94].

Other side-effects are even more unusual and include allergic reactions, pseudomembranous colitis (as with other broad-spectrum antibiotics) [95] and transient sensorineural deafness, particularly if erythromycin is used in high dosage in elderly patients with renal insufficiency [96]. This toxic effect may be augmented by concurrent cimetidine therapy [97].

Drug interactions may occur as a result of the propensity of erythromycin to inhibit hepatic metabolism (cytochrome P450 enzymes). This may cause toxic accumulation of various drugs, including theophyllines, midazolam, digoxin, disopyramide and carbamazepine, and the potentiation of warfarin and glucocorticoids [90,98,99]. For the same reason, erythromycin should not be given with terfenadine or astemizole, the accumulation of which may rarely lead to ventricular dysrhythmias [90]; indeed, intravenous erythromycin itself has rarely been associated with torsades de pointes [100]. Cyclosporin levels may also be increased.

#### *Principal uses in respiratory medicine*

Erythromycin or another macrolide may be used in the treatment of community-acquired pneumonia, both when there is a history suggestive of penicillin allergy and when a decision is taken to cover infection caused by intracellular organisms such as *Legionella pneumophila* and *Chlamydia* spp. or the pathogen *Mycoplasma pneumoniae* (see Chapter 13) [77]. It has been used to treat acute bronchitis and acute infective exacerbations of chronic bronchitis, although resistant strains of *H. influenzae* are increasingly encountered, against which clarithromycin and azithromycin are better equipped. It may also be used for upper respiratory tract infection as an alternative to penicillin.

#### *Clarithromycin*

Clarithromycin is an erythromycin derivative with a 14-membered ring. The antimicrobial activity of clarithromycin is enhanced by an active 14-hydroxy metabolite [101]. Clarithromycin has the same mode of action but better pharmacokinetics than erythromycin. It is more acid-stable than its parent drug and is rapidly absorbed with good serum and tissue levels, its longer half-life (5–7 h) permitting twice-daily dosing. The lower total dosage results in a reduced incidence of gastrointestinal side-effects.

*Spectrum of activity against respiratory pathogens*

This is broadly similar to erythromycin except that clarithromycin and its metabolite together have enhanced activity against *H. influenzae* and *Moraxella catarrhalis*. It also has slightly improved *in vitro* activity against *Legionella* and *Chlamydia* spp. It is effective against *Mycoplasma pneumoniae* and may also be used in combination with other drugs to treat *Mycobacterium avium-intracellulare* infection, against which it is four times more active than azithromycin *in vitro*. Those streptococci and staphylococci resistant to erythromycin are also resistant to the newer macrolides.

*Administration, distribution and excretion*

Clarithromycin is available in tablet form, as a suspension and as a reconstitutable powder for intravenous infusion. It is well absorbed with or without food. Hepatic metabolism produces the pharmacologically active 14-hydroxy-clarithromycin mentioned above. Significant amounts of both clarithromycin and its active metabolite are excreted unchanged in the urine, so that dose adjustment may be needed in severe renal failure but not in liver disease. Adequate serum and tissue levels are achieved.

*Dosage*

The usual oral dose of clarithromycin is 250 mg twice daily, giving a peak blood level equivalent to 500 mg erythromycin [102]. The intravenous dose is 500 mg twice daily.

*Adverse effects*

These are broadly similar to erythromycin except that gastrointestinal symptoms are less common [102]. Thrombophlebitis also occurs with intravenous clarithromycin. Drug interactions are also similar (cytochrome P450). Clarithromycin may reduce concentrations of zidovudine. In the respiratory context, both theophyllines and warfarin are commonly potentiated, as is rifabutin so that uveitis or a polyarthralgia syndrome may occur with this drug.

*Principal uses in respiratory medicine*

These are similar to erythromycin. The drug is used in community-acquired pneumonia, particularly where there is a history of penicillin allergy, and may also be effective in acute bronchitis and sinusitis. Clarithromycin is more likely to deal with *H. influenzae* in exacerbations of chronic bronchitis. The newer macrolides have been the most important advance in the treatment of opportunistic mycobacterial disease since rifampicin. Clarithromycin is

the cornerstone in regimens used to treat infections caused by organisms of the *Mycobacterium avium-intracellulare* complex, including the disseminated bacteraemic form of this infection that occurs in patients with AIDS [103–105]. In treating this infection in immunocompetent patients (see Chapter 20), clarithromycin may be given at a dose of 500 mg twice daily for 18–24 months or more in combination with rifampicin (or rifabutin) and ethambutol, sometimes with a fourth drug such as ciprofloxacin or clofazimine. An aminoglycoside such as amikacin or streptomycin is sometimes used as a fourth drug for part of the course [106]. Ethionamide or cycloserine have been used occasionally but tend to be avoided because of their toxicity [106]. One study has shown that the three-drug combination of clarithromycin, rifabutin and ethambutol is more effective at clearing *Mycobacterium avium* complex bacteraemia and prolonging survival in patients with AIDS than a four-drug regimen comprising rifampicin, ethambutol, clofazimine and ciprofloxacin [107]. Clarithromycin is also active against *Mycobacterium kansasii* and although the standard regimen for these infections comprises rifampicin, ethambutol and isoniazid, clarithromycin may be useful in resistant cases [106].

*Azithromycin*

Azithromycin is the first member of a group of macrolides known as azalides (because of the insertion of a nitrogen atom in the macrolide nucleus) and is an acid-stable semi-synthetic erythromycin derivative with a 15-membered ring. The drug achieves very low serum levels in comparison with other macrolides but is rapidly and highly concentrated intracellularly, particularly in neutrophils and macrophages, and it has been suggested that these cells may help to transport the drug to sites of infection [108]. Azithromycin has a long terminal serum elimination half-life of about 57 h, high tissue concentrations persisting for up to 5 days following a single oral dose, suggesting that significant bacterial activity in tissues persists for this length of time after a short course [109].

*Spectrum of activity against respiratory pathogens*

This is broadly similar to erythromycin except that azithromycin has greater *in vitro* activity against *H. influenzae* and *Moraxella catarrhalis* than both erythromycin and clarithromycin [65,108]. Activity against *Strep. pneumoniae* is similar to other macrolides. It is active against *Legionella* and *Chlamydia* spp., as well as *Mycoplasma pneumoniae*. It is less active *in vitro* than clarithromycin against *Mycobacterium avium-intracellulare* [110]. Those streptococci and staphylococci resistant to erythromycin are also resistant to the newer macrolides.

### Administration, distribution and excretion

Azithromycin is available as 250mg capsules, 500mg tablets and as an oral suspension. Absorption is reduced by food. Serum concentrations are low but concentrations in lung and sputum are high. Some hepatic metabolism takes place but most of the drug is excreted unchanged in the gut, presumably via the biliary tract. There is a small amount of renal excretion but dose modification is not required in patients whose creatinine clearance exceeds 40mL/min. Data are currently unavailable for severe renal failure.

### Dosage

The recommended oral dose of azithromycin in respiratory infections is 500mg once daily for 3 days. The dose should be taken *between* meals (1h before or 2h after) as the presence of food or antacids in the stomach reduces absorption significantly [111]. This is probably as effective as an alternative regimen that uses 500mg on day 1 and 250mg on days 2–5 [108]. Compliance is likely to be greater in such short once-daily regimens [112]. There is as yet no intravenous formulation.

### Adverse effects

These are broadly similar to erythromycin except that gastrointestinal symptoms are less common [108]. Headaches and dizziness occasionally occur. Azithromycin appears to have no affinity for the hepatic cytochrome (P450) enzymes responsible for some of the drug-enhancing effects common to both erythromycin and clarithromycin. It may therefore be used without increasing the levels of theophylline, warfarin, glucocorticoids and carbamazepine [110]. There also appears to be no interaction with terfenadine [108]. Cyclosporin levels may be increased.

### Principal uses in respiratory medicine

These are similar to clarithromycin. Azithromycin is the macrolide with the greatest *in vitro* activity against *H. influenzae* and *Moraxella catarrhalis*. This drug has also been used in regimens used to treat *Mycobacterium avium-intracellulare* [103,104], including the disseminated form of this infection that occurs in patients with AIDS [106], although it has less *in vitro* activity against these organisms than clarithromycin. A dose of 500mg once daily has been used in the treatment of *Mycobacterium avium* complex (see Chapter 20) in combination with other drugs as outlined for clarithromycin [106]. Low blood, as opposed to intracellular, levels are a theoretical concern in the treatment of patients with community-acquired pneumonia who may be bacteraemic.

### Other macrolides

Roxithromycin and dirithromycin are both structural modifications of erythromycin and there are others worldwide. The spectrum of activity of roxithromycin is similar to that of erythromycin but its pharmacokinetics and tolerance are improved, permitting a dose regimen of 300mg daily as single or two divided doses [65]. Excretion is hepatobiliary and dose modification is needed in hepatic but not renal failure. The pharmacokinetics of dirithromycin permits a dose regimen of 500mg once daily. They both have relatively poor activity against *H. influenzae* and dirithromycin is ineffective against *Legionella* spp. [65]. Neither drug is available in the UK.

### Trimethoprim

Trimethoprim, a synthetic broad-spectrum antimicrobial, is a diaminopyrimidine of similar structure to the antimalarial compound pyrimethamine. It was originally developed to potentiate the effect of sulphonamides and was at first only available in combined form with sulfamethoxazole (sulphamethoxazole) as co-trimoxazole. Ten years later, following doubts about the *in vivo* validity of *in vitro* synergism between these drugs and because of concern about the side-effects of the sulphonamide component of co-trimoxazole, trimethoprim was made available as a single agent that is now recognized to have potent antibacterial properties when used alone.

### Mode of action

Trimethoprim has a slow bactericidal action by causing inhibition of the enzyme dihydrofolate reductase, which is necessary in bacterial amino acid synthesis for the conversion of folate to folinic acid. Although this enzyme is also possessed by humans, trimethoprim has up to 100 000 times more inhibitory action against the bacterial form than against the human enzyme, so that normal folate metabolism is not usually significantly upset (see Adverse effects). Sulphonamides also act on the same metabolic pathway but one step earlier (Fig. 9.4).

### Spectrum of activity against respiratory pathogens

Trimethoprim has a wide range of activity *in vitro* against most Gram-positive cocci and Gram-negative bacilli. Amongst the common respiratory pathogens, *Strep. pneumoniae*, *H. influenzae* and *Moraxella catarrhalis* are still usually sensitive but becoming less so. However, *Ps. aeruginosa* is inherently resistant and the drug has no useful activity against anaerobes. Resistance can also develop during treatment by a variety of mechanisms, as is the case with other antimicrobial agents and the number of isolates of resistant *H. influenzae* had increased from

0.2% in 1977 to 1.4% in 1981 according to a British survey [113,114]. It is not clear whether the release of trimethoprim from its sulphonamide partner has increased this likelihood.

#### Administration, distribution and excretion

It is usual to prescribe trimethoprim orally and 100 mg or 200 mg tablets are available as is a liquid suspension. A parenteral preparation is available in the UK but not the USA.

The drug is well absorbed when taken by mouth and is widely distributed. It is highly lipid soluble and therefore tends to achieve better tissue concentrations than sulfamethoxazole, so that when taken in compound form the blood levels of trimethoprim are lower than those of the sulphonamide. By the same token, trimethoprim achieves higher levels in pleural fluid and bronchial secretions than in the blood. Provided that renal function is normal, about 70% of a given dose of trimethoprim is excreted in the urine within 24 h. The majority of this is in active form, about 8% being conjugated and inactive. Some trimethoprim is excreted in bile. The plasma half-life is about 10 h but is prolonged in renal insufficiency, in which case dose modification or omission may be necessary.

#### Dosage

The usual dose is 200 mg 12-hourly by mouth. If the creatinine clearance is 15–30 mL/min, the dose should be reduced to 50 mg 12-hourly; if the creatinine clearance falls below this level, trimethoprim should not be given.

#### Adverse effects

About 6% of patients experience some nausea, taste disturbance, abdominal discomfort, vomiting or diarrhoea, and about 4% develop rashes [115]. The likelihood of these relatively minor problems occurring is increased at higher doses or if the course of treatment is prolonged. Although there is a theoretical risk of the development of folate deficiency, since the drug is much more active against bac-

terial rather than host dihydrofolate reductase it seems that this problem only occurs in patients who are relatively folate depleted before treatment; nevertheless, if prolonged treatment is required, regular blood counts are advisable. If clinical evidence of folate deficiency does develop, it can be corrected with folinic acid without countering the drug's antibacterial action [116]. There is no evidence of teratogenicity but alternative antimicrobial agents are advised in pregnancy [117].

It is believed that most of the side-effects arising from the use of co-trimoxazole have been from the sulphonamide component; however, for further possible trimethoprim-related adverse effects, including hyperkalaemia, the reader is referred to the following section on co-trimoxazole.

#### Principal uses in respiratory medicine

Trimethoprim is still sometimes used in the treatment of acute purulent exacerbations of chronic bronchitis, usually as a second-line agent in cases that have either failed to respond to a first-line drug (e.g. amoxicillin) and/or when *in vitro* sensitivities indicate that trimethoprim is the more appropriate antimicrobial. Published work has indicated that trimethoprim alone is as effective in this respect as co-trimoxazole and that it produces fewer side-effects [118]. This apparent efficacy is in keeping with the drug's activity against the common pathogens of chronic bronchitis, namely *Strep. pneumoniae* and *H. influenzae*. The clinical efficacy of trimethoprim alone for treating pneumonia is unproven.

Another use of trimethoprim has been in combination with dapsone (see below) as an alternative to high-dose oral co-trimoxazole in the treatment of mild to moderate *Pneumocystis carinii* pneumonia.

#### Co-trimoxazole and *Pneumocystis carinii* pneumonia

Trimethoprim was originally available only in combined form with the sulphonamide sulfamethoxazole, as the two compounds together were shown to greatly potentiate

Fig. 9.4 Sites of action of sulphonamides and trimethoprim.

each other's *in vitro* antibacterial activity. There are now considerable doubts about whether this laboratory observation translates into improved clinical potency *in vivo*, at least in the treatment of acute exacerbations of chronic bronchitis [118]. This drug combination remains the first-choice treatment in immunocompromised patients with *Pneumocystis carinii* infection (see also section on pentamidine and Chapter 52).

#### Mode of action

The mode of action of trimethoprim has been outlined above. Sulfamethoxazole acts on the same metabolic pathway, but one step earlier, by inhibiting the bacterial enzyme dihydropteroate synthetase (Fig. 9.4), which is necessary for the conversion of *p*-aminobenzoic acid to dihydrofolic acid. This enzyme does not occur in humans, who therefore require dietary folate. The optimal *in vitro* concentration ratio of sulfamethoxazole to trimethoprim was found to be 20:1, this being the ratio of their MICs for most organisms. However, because of the greater diffusibility of trimethoprim, which is dispersed in body water more widely than sulfamethoxazole, the available preparations of co-trimoxazole have been formulated in a 20:4 (5:1) ratio that has been found to reproduce the 20:1 ratio most closely in plasma.

Sulphonamides are principally bacteriostatic while trimethoprim may act bactericidally, and the rationale for the compound preparation was that this bactericidal effect was more likely to occur with the combined form.

#### Spectrum of activity against respiratory pathogens

The spectrum of activity of co-trimoxazole is similar to that of trimethoprim except that the susceptibilities of both Gram-positive and Gram-negative organisms to co-trimoxazole *in vitro* are greater than to trimethoprim alone. Like trimethoprim, co-trimoxazole has no useful activity against *Ps. aeruginosa* and the majority of anaerobes. The combination has also been shown to be active against the fungal organism *Pneumocystis carinii* and against the actinomycetes *Nocardia* spp. (see p. 210).

#### Administration, distribution and excretion

Co-trimoxazole may be administered by mouth or intravenously. The pharmacokinetics of trimethoprim have already been summarized. Sulfamethoxazole, although selected as a sulphonamide with pharmacokinetic behaviour most closely resembling that of trimethoprim, is well absorbed orally but less well distributed in total body water. Like trimethoprim it is excreted in urine, 70% being recoverable as metabolite and 30% unchanged. It too accu-

mulates in renal insufficiency, in the presence of which the dose may need to be reduced (see below).

#### Dosage

The usual dose for exacerbations of chronic bronchitis was 160 mg trimethoprim and 800 mg sulfamethoxazole (expressed as 960 mg co-trimoxazole) every 12 h. These amounts were given as two 'single-strength' (80/400) tablets or in one 'double-strength' (160/800) tablet of co-trimoxazole, the duration of a course being about 1 week. However, co-trimoxazole is no longer recommended for this purpose by the UK Committee on Safety of Medicines unless a good reason can be demonstrated (see p. 210).

Much higher levels of co-trimoxazole are required to treat *Pneumocystis carinii* pneumonia (PCP), the daily dose being 20 mg/kg of trimethoprim and 100 mg/kg of sulfamethoxazole. It is usual to administer the co-trimoxazole as three or four divided doses and to treat for 2 weeks in the case of non-AIDS-associated PCP and 3 weeks in the presence of HIV infection, provided that the therapy is tolerated (see Chapter 52). A course of co-trimoxazole is conventionally given intravenously at first at this 120 mg/kg daily dose until clinical improvement occurs, after which the course is completed orally as the drug combination is well absorbed. Milder cases may be treated orally from the outset [119]. Dosage reductions should be made in renal failure as above. A full dose can be given if the estimated creatinine clearance (ECC; see Eqn 9.1, p. 215) is greater than 30 mL/min, the dose being halved when the ECC is 15–30 mL/min and omitted completely when the ECC is less than 15 mL/min. The necessity for 3-week courses has been questioned and it may well be possible to conclude treatment after 2 weeks in the face of adverse effects if the patient has apparently responded and provided that secondary prophylaxis is started at the conclusion of the course [120].

Prophylaxis using a once-daily or three times weekly (Monday/Wednesday/Friday) oral dose of co-trimoxazole 960 mg or a once-daily dose of 480 mg is commonly used in immunosuppressed patients to reduce the chance of PCP becoming established [119,121]. All have been shown to be effective and the lower doses are better tolerated [122]. In HIV infection such intervention is recommended:

- 1 when the CD4 (T-helper) lymphocyte count falls below  $0.2 \times 10^9/L$ ;
- 2 if the ratio of CD4 to total lymphocytes is less than 1:5;
- 3 where there is oral thrush or an unexplained fever;
- 4 where there is an AIDS defining diagnosis such as Kaposi's sarcoma, cerebral toxoplasmosis or cryptococcal meningitis;
- 5 in a patient who has recovered from a previous episode of PCP [119].

### Adverse effects

The incidence of side-effects from standard dosage was found to be 8% in a survey of 30 000 patients [123]. These are usually minor when the preparation is used at this original dosage and it is generally supposed that the sulphonamide component is responsible for more mischief than the trimethoprim [124], although hyperkalaemia is one possible exception. Co-trimoxazole produces nausea and other mild gastrointestinal symptoms in 3–4% of recipients. Cutaneous rashes occur in a similar percentage. Serious cutaneous eruptions such as erythema multiforme (Stevens–Johnson syndrome) are fortunately rare [125]. Interference with folate metabolism may produce megaloblastic anaemia in patients who are already bordering on folate deficiency, such as pregnant women, alcoholics and epileptics taking phenytoin. Both components of co-trimoxazole are potentially toxic to bone marrow, and bone marrow aplasia, leucopenia and thrombocytopenia have been described. Fatalities due to these blood dyscrasias have rarely been attributed to co-trimoxazole. Other unusual side-effects include acute interstitial nephritis, crystaluria (which may occur in situations of low urine flow, with metabolites of co-trimoxazole precipitating in the renal tubules) and cholestatic jaundice [126].

Side-effects are very much more commonly encountered with the high doses of co-trimoxazole required for the treatment of PCP, where over 30% of patients may need to discontinue treatment before the course is completed [127–129]. Hyperkalaemia may occur in about 20–50% of patients with AIDS when they are being treated with high-dose trimethoprim in combination with sulfamethoxazole or dapsone [129]. This is probably due to the mild potassium-sparing diuretic effect of the trimethoprim molecule, which is structurally related to both amiloride and triamterene, this effect only becoming clinically evident when the drug is used at high dosage [130].

Drug interactions, with potentiation of the effects of warfarin, oral hypoglycaemics, rifampicin and phenytoin, may occur as a result of competition for protein-binding sites.

### Principal uses in respiratory medicine

Co-trimoxazole has been used in similar fashion to trimethoprim, as a treatment for patients with acute infective exacerbations of chronic bronchitis [131]. Despite the *in vitro* superiority of co-trimoxazole, no clinical trial has ever convincingly demonstrated its superiority in this respect over trimethoprim alone [115]. This may in part be due to the rather poor tissue penetration of sulfamethoxazole, so that although the plasma ratio may be optimal the ratios in lung tissue are not, with the result that the *in vitro*

situation is therefore not reproduced. A further theoretical reason for the combined preparation, over and above that of synergy, was to diminish the development of resistant strains. However, this may not be borne out in practice, since countries such as Finland, where trimethoprim has been available as a single agent for many years, do not appear to have a higher proportion of resistant strains than those countries where separation of the two drugs was made relatively recently [132]. In the UK, the Committee on Safety of Medicines has ruled that co-trimoxazole, while remaining the treatment of choice in PCP and being indicated in toxoplasmosis and nocardiosis, should only be used in acute exacerbations of chronic bronchitis 'when there is bacteriological evidence of sensitivity to co-trimoxazole, and good reason to prefer this combination of drugs to a single antibiotic' [133].

Co-trimoxazole is the agent of choice in the treatment of PCP, the most common treatable pneumonic infection in AIDS, corticosteroid treatment being started at the same time in the hypoxic patient provided that the diagnosis is secure. Second-line agents for the iller patient who fails to respond or cannot tolerate the drug include pentamidine or trimetrexate/folinic acid with dapsone, if the patient can take oral therapy. Second-line agents for treatment of mild to moderate cases of PCP include dapsone/trimethoprim and clindamycin/primaquine.

Co-trimoxazole is also used prophylactically to prevent PCP in immunosuppressed patients, such as those with HIV infection (see above), and in those receiving immunosuppressant treatment for a variety of conditions, such as acute lymphocytic leukaemia or following organ transplantation in order to prevent rejection [121]. For an account of the clinical management of PCP the reader is referred to Chapter 52.

### Tetracyclines

Tetracyclines were the second 'broad-spectrum' antibiotics to become available, chloramphenicol being the first. Their usefulness in respiratory medicine has declined with the gradual emergence of resistant strains among common pathogens such as *Strep. pneumoniae*, and with growing concern about their safety in patients, often the elderly, who have relative renal insufficiency. They retain a high degree of activity against organisms responsible for 'atypical pneumonia'. Each member of the group has a basic structure of four fused benzene rings (Fig. 9.5), various side-chain substitutions accounting for their different pharmacokinetic properties [134]. There are six generic compounds listed in the *British National Formulary*: tetracycline, oxytetracycline, demeclocycline, lymecycline, minocycline and doxycycline [58]. Research has produced two new developmental synthetic glycyclines that are more active against those strains of *Strep. pneumoniae* and *H. influenzae* that have become resistant to

Fig. 9.5 Tetracycline nucleus.

existing tetracyclines but it remains to be seen whether these drugs go into commercial production [69]. The tetracyclines are primarily bacteriostatic antimicrobial agents that have their action by inhibiting microbial protein synthesis.

The tetracyclines may be grouped in terms of their duration of action. The early compounds tetracycline and oxytetracycline have elimination half-lives of 7–10 h and require 6-hourly administration. The newer (and more expensive) tetracyclines have longer half-lives of 17–22 h, so that doxycycline can be given once daily. The other tetracyclines fall at various points between these extremes.

#### *Spectrum of activity against respiratory pathogens*

The spectrum of activity of all the tetracyclines is rather similar and although some of the more recent members may have greater *in vitro* activity [135], the significance of this in clinical practice is unclear. Although retaining activity over a very wide range of microorganisms, significant resistance continues to be reported among common respiratory pathogens. By 1975, 13% of *Strep. pneumoniae* were found to be resistant across the country [136]. Almost one-quarter of pneumococcal isolates were resistant at one hospital in Liverpool 30 years ago [137] and wide geographical differences in susceptibility have been noted. An even higher resistance rate for *Strep. pyogenes* has been found (36%) [136], and tetracyclines are therefore unlikely to be effective in streptococcal pharyngitis. They are active against *H. influenzae*, although resistant strains of this organism also occur. Doxycycline has been used to treat *Legionella* pneumonia [138], although there is more experience with macrolides. Tetracyclines are effective against *Mycoplasma pneumoniae*, *Chlamydia* spp. and *Coxiella burnetii* as well as rare causes of respiratory infection such as *Francisella tularensis*, *Brucella* spp. (with an aminoglycoside), *Ps. pseudomallei*, *Yersinia pestis* and the causes of rickettsial and leptospiral pneumonias (see Chapter 13).

#### *Administration, distribution and excretion*

Tetracyclines are usually administered orally but, with the exception of minocycline and doxycycline, absorption

may be inhibited by food so that they should be taken before meals. Absorption is also reduced by milk, calcium, aluminium, bismuth, magnesium and zinc salts, antacids, and oral iron, sucralfate and quinapril, so that tetracyclines should not be taken within 2 h of these substances.

Tetracyclines are distributed widely in body fluids in much the same way as penicillins and reach appreciable concentrations in sputum, pleural fluid and paranasal sinuses. Oral administration is satisfactory for most clinical application and an intravenous preparation of tetracycline is no longer available in the UK. Oxytetracycline, minocycline and doxycycline preparations for intravenous use may be obtained in the USA. Intramuscular injection of tetracyclines is painful.

The main excretion route for most tetracyclines is via the kidneys, so that accumulation may occur in renal failure. Such accumulation does not occur with doxycycline, which is excreted in the bowel in these circumstances and can be used in renal insufficiency [139].

#### *Dosage*

The usual dose of short-acting tetracycline is 1 g daily in four divided doses. The longer-acting tetracyclines may be given in smaller doses, that of doxycycline being 100 mg once daily and minocycline 100 mg twice daily.

#### *Adverse effects and interactions*

The commonest side-effects are minor and related to gastrointestinal tract irritation, with nausea, abdominal discomfort and vomiting. Non-specific diarrhoea may occur and is rarely accompanied by staphylococcal enterocolitis or pseudomembranous colitis. Monilial infection of mucosal surfaces is common as with other broad-spectrum antibiotics. Allergic reactions are rare but photosensitivity may occur especially with demeclocycline (demethylchlortetracycline). Minocycline may cause a greyish-black skin pigmentation.

Tetracyclines may be deposited in growing bone and in new tooth enamel, producing brown discoloration [140,141]; for this reason they should be avoided in children under the age of 12 years and in pregnant and nursing women, as they also cross the placenta and are secreted in breast milk.

Tetracyclines may exacerbate systemic lupus erythematosus and should be avoided in this condition [142].

Hepatotoxicity is rare but has been produced with fatal consequences when large (more than 2 g daily) doses have been given parenterally or when the drug has accumulated as a result of renal insufficiency [143]. Minocycline may have the least potential for worsening liver damage but even with this drug rare idiosyncratic reactions leading to liver failure have been described [144].

Pre-existing renal insufficiency may be worsened by

tetracycline [145,146], although doxycycline does not accumulate in renal failure and is apparently safe in this respect. These effects are related to the degree of pre-existing renal failure, the dose used and the duration of therapy. Demeclocycline may produce nephrogenic diabetes insipidus and this property has been applied to clinical advantage in the management of inappropriate antidiuretic hormone (ADH) secretion.

Reversible dizziness and vertigo may occur with minocycline [147]. Benign intracranial hypertension is reported with its long-term use and eosinophilic pulmonary infiltrates have been reported, although these are rare [148,149].

The efficacy of oral contraceptives may be reduced during and for 7 days after a course of tetracycline. Warfarin may be potentiated and blood levels of cyclosporin are increased.

#### *Principal uses in respiratory medicine*

The use of tetracyclines declined in respiratory medicine once these drugs were no longer considered to be first-choice antimicrobial agents in exacerbations of chronic bronchitis. However, they are still extensively used worldwide for this purpose, sometimes on the grounds of cost, although resistant *Strep. pneumoniae* are more likely to be encountered than with amoxicillin or trimethoprim; 3–23% of pneumococcal isolates are resistant as are 1–6% of isolates of *H. influenzae*, while *Moraxella catarrhalis* is usually susceptible. They remain active in chlamydial and mycoplasma pneumonias and in Q fever [150]. In practice, however, the organisms responsible for these infections are frequently covered by erythromycin or a newer macrolide and these drugs also have the added advantage of being the antimicrobials of choice in *Legionella* pneumonia and of retaining a good degree of activity against *Strep. pneumoniae* and *H. influenzae*, particularly in the case of the newer macrolide compounds.

Demeclocycline is sometimes used in the treatment of inappropriate ADH secretion, while doxycycline is relatively safe in renal failure. Minocycline is probably the safest tetracycline to use in hepatic insufficiency but care should nevertheless be exercised (see above).

Tetracycline is commonly used as a local intrapleural irritant (1g tetracycline hydrochloride in 50mL 0.9% saline made up to 60mL in a syringe with 10mL 10% lidocaine) to produce a chemical pleurodesis in the management of malignant pleural effusions, although it is claimed that talc (which may be injected with water as a slurry) is more likely to be effective.

### **Aminoglycosides**

Aminoglycosides occupy an important position in the

treatment of serious infection, particularly in Gram-negative sepsis. Gentamicin is the most widely used member of the group, which also contains tobramycin, netilmicin, amikacin and kanamycin. Streptomycin and neomycin are also aminoglycosides; the former, the original member of the group, is now mainly used as a second-line antituberculous drug and the latter as a minimally absorbed oral preparation for bowel sterilization, it being too toxic for parenteral use. All aminoglycosides are chemically related by the possession of an aminocyclitol ring. Those whose generic names contain the root ‘-mycin’ owe their original synthesis to a species of *Streptomyces*, whereas those containing ‘-micin’ such as gentamicin have been derived from *Micromonospora* spp.

#### *Mode of action*

Aminoglycosides are bactericidal, causing the inhibition of microbial protein synthesis by binding intracellularly to RNA subunits, thereby interfering with normal ribosomal activity. Bacteria may become resistant to them by various mechanisms including the production of enzymes that alter the drug’s structure. Microbial resistance to gentamicin is becoming an increasing problem in some countries.

#### *Spectrum of activity against respiratory pathogens*

The principal area of activity of the aminoglycosides is against aerobic (or facultatively anaerobic) Gram-negative bacilli, including the Enterobacteriaceae *E. coli* and *Klebsiella*, *Proteus*, *Serratia*, *Yersinia* and *Citrobacter* spp. Gentamicin, tobramycin, amikacin and netilmicin are also active against *Ps. aeruginosa*. Kanamycin is not and its usefulness is therefore severely limited. Streptomycin is not used in the treatment of Gram-negative sepsis because of the rapid emergence of microbial resistance. None of the aminoglycosides are effective against anaerobic infection, which should be treated with penicillin or metronidazole if this is thought to be a possibility.

Aminoglycosides also have useful activity against methicillin-sensitive *Staph. aureus*, although they are not a first-line drug for known infection by this organism, which is susceptible to effective and less toxic alternatives. However, aminoglycosides may play an important supportive role in the treatment of serious *Staph. aureus* infection.

Aminoglycosides have only weak activity against *Strep. pneumoniae*, *Strep. pyogenes* and *H. influenzae*, which need separate antimicrobial cover according to clinical circumstances when gentamicin is being used empirically in the treatment of severe bacteriologically undiagnosed infection. Despite their inactivity against streptococci when used alone, their combination with a  $\beta$ -lactam antibiotic may increase the susceptibility of these organisms, this

being the basis for their synergistic use with penicillins in streptococcal and staphylococcal endocarditis. Such combined use with  $\beta$ -lactams may also produce synergism for Gram-negative organisms, as well as broadening cover and reducing the frequency with which resistant organisms emerge.

*Distribution, administration and excretion*

Aminoglycosides are widely distributed in body fluids but achieve levels in bronchial secretions only one-fifth as high as those in plasma [151], an observation that has led some clinicians to administer the drugs by intratracheal instillation or nebulization (see below) in serious persistent Gram-negative infection, such as may occur in patients with cystic fibrosis infected by *Ps. aeruginosa* [152–154]. Intracellular concentrations of aminoglycoside are low following parenteral administration, with the notable exception of the proximal renal tubular cells which are susceptible to toxic damage.

Gentamicin, tobramycin, amikacin and netilmicin may all be given either intramuscularly or intravenously. Absorption after intramuscular injection is rapid, provided that tissue perfusion is normal, peak plasma concentrations being reached in about 60 min. Intravenous injection may be direct, via a cannula over about 3 min, or alternatively by infusion over 20–30 min. If aminoglycosides are infused they should not be mixed in the same solution with  $\beta$ -lactam antibiotics because they bind and inactivate each other [155]; furthermore, infusions lasting more than 30 min are inadvisable in terms of the achievement of optimum drug levels. The peak level may be assayed 60 min after the onset of an intravenous injection or infusion, as this allows sufficient time for diffusion from the vascular space into extravascular fluid compartments [156]. The bactericidal effect is heavily concentration dependent, so that peak concentrations have been shown to correlate with clinical and bacteriological response [157]; indeed in serious sepsis, the peak aminoglycoside level should be about eight times the MIC of the target pathogen or pathogens [158]. The effectiveness of such transient high peak concentrations is the reason for current recommendations regarding once-daily dosing with aminoglycosides (see p. 214) and contrasts with  $\beta$ -lactams, where the length of time that the antibiotic spends above the MIC for the target organism, rather than peak concentration, governs clinical success. The trough concentrations of aminoglycoside are largely irrelevant with regard to clinical effect but have to be watched closely to avoid toxicity.

The pharmacokinetics of parenterally administered aminoglycosides are somewhat complex but for practical purposes they undergo no metabolism and are excreted in the urine unchanged, the principal phase of excretion

being governed by the glomerular filtration rate, which results in a half-life of about 2 h in a subject with normal renal function. A much smaller proportion of the drug is eliminated more slowly over the space of a week or more, possibly as a result of slow intracellular losses [159]. Perhaps in part as a consequence of their pharmacokinetics, aminoglycosides may demonstrate a 'postantibiotic effect', i.e. bacterial growth of susceptible organisms remains suppressed after only a short exposure. The combination with  $\beta$ -lactam antibiotics may increase the postantibiotic effect.

One study showed that the levels of aminoglycoside in bronchoalveolar lavage fluid following the topical administration of 80 mg tobramycin by jet nebulizer exceeded the MIC for most pathogenic organisms despite very low or undetectable tobramycin levels in the blood [160].

*Adverse effects*

The aminoglycosides need to be administered cautiously as their therapeutic and toxic plasma levels are close, i.e. they have a low therapeutic index. Their two principal side-effects are renal tubular necrosis and ototoxicity.

*Renal toxicity.* Treatment with aminoglycosides is a relatively common cause of acute renal failure due to tubular necrosis [161]. These drugs are reabsorbed in the proximal renal tubules so that their concentration in the renal cortex may exceed their plasma concentration 10–50 fold. Tissue levels of aminoglycoside tend to creep up gradually during a prolonged course, even though the serum levels may remain within a given band. Any consequent renal cortical damage may be guarded against provided that reasonable precautions are taken:

- 1 measurement of serum aminoglycoside levels, which should be kept within the target range for the given drug;
- 2 monitoring of the plasma creatinine/urea;
- 3 avoidance, where possible, of drugs that may enhance the nephrotoxicity of aminoglycosides (Table 9.4) or, where such avoidance is not possible, the administration of such drugs as far apart from the aminoglycoside dose as the clock allows;

**Table 9.4** Drugs that may enhance the nephrotoxicity of aminoglycosides.

4 use of once-daily dosage regimens in certain given circumstances (see below).

Nephrotoxicity is more likely to occur with prolonged courses, in the elderly, in the presence of hypotension or in subjects with pre-existing renal insufficiency [162]. When such renal insufficiency is present, aminoglycosides may be continued if they are considered essential and if no suitable non-nephrotoxic alternative antimicrobial is available. The usual practice is to increase the length of time between doses and this is discussed more fully below. Renal insufficiency is usually reversible if the drug is stopped, although recovery may be slow.

*Ototoxicity.* Although of less critical importance, ototoxicity may nevertheless result in significant impairment of hearing and/or balance. It may occur in the absence of nephrotoxicity. Hearing loss is due to cochlear damage and may be potentiated if loop diuretics, particularly etacrynic (ethacrynic) acid, are used concurrently. Vestibular effects include feelings of dizziness, vertigo, nausea and vomiting. Disturbances of balance resulting in gross ataxia may sometimes be produced and may only become evident when the patient has recovered sufficiently to get out of bed. These effects may be worse when visual compensation is reduced, such as in the dark or on face-washing over a basin. Vestibular damage is due to destruction of the hair cells in the inner ear [163]. Ototoxicity may be irreversible, although patients may learn to compensate for their unsteadiness to some extent. It may arise despite seemingly satisfactory serum concentrations. It is likely to occur only with prolonged administration [164] (e.g. infective endocarditis) and is therefore not commonly seen in respiratory medical practice. The chances of these adverse effects are minimized by careful attention to serum levels but it may be as well to warn patients of the risks if a prolonged course of treatment is considered necessary [165].

*Other side-effects.* The aminoglycosides are mild neuromuscular blockers and may therefore potentiate the effect of anaesthetic relaxants such as succinylcholine. They should not be used in patients with myasthenia gravis unless there is no alternative, and then only if facilities for mechanical ventilation are available. Prolonged aminoglycoside administration may cause hypomagnesaemia. Aminoglycosides cross the placenta and if used in pregnancy may result in fetal eighth cranial nerve damage. Allergic reactions are rare.

#### *Choice of aminoglycoside*

Various claims have been made with regard to greater antimicrobial activity or diminished likelihood of toxicity with this or that agent, but there are no substantial differences in terms of clinical efficacy or nephrotoxicity

between gentamicin, tobramycin, netilmicin and amikacin. Kamamycin suffers from the fundamental drawback of lack of efficacy against *Ps. aeruginosa*. The deficiencies of streptomycin and neomycin as Gram-negative antimicrobial agents have been mentioned above. The choice between the remaining four aminoglycosides may therefore be reasonably made on the grounds of the *in vitro* sensitivities and cost of treatment.

#### *Principal uses in respiratory medicine*

Aminoglycosides are often used in combination with a  $\beta$ -lactam antibiotic for the treatment of serious hospital-acquired pneumonia (see Chapter 13) and the treatment of patients with chronic bronchial infection by susceptible organisms occurring in association with cystic fibrosis (see Chapter 30) or other forms of bronchiectasis. Streptomycin and amikacin are occasionally used as supportive agents in resistant forms of tuberculous and non-tuberculous (opportunistic) mycobacterial disease (see Chapters 19 & 20).

#### *Gentamicin*

Gentamicin is the aminoglycoside of first choice for Gram-negative bacillary infection, largely because its patent expired a long time ago and is therefore presently cheaper than the other drugs of the same class. It can be given intravenously or intramuscularly. Bolus dosage or intermittent infusion are more likely to produce therapeutic levels than continuous infusion, which should be avoided [151].

#### *Divided or extended dosage regimens*

A loading dose of 2 mg/kg may be given initially, irrespective of renal function, in order to achieve an adequate plasma level [166]. Thereafter it has been common practice to administer a total daily dose of up to 5 mg/kg in two or three divided doses, provided that the patient's renal function is normal. Peak and trough serum levels may be checked after the second or third maintenance dose and, provided that these are satisfactory, renal function is monitored with twice-weekly creatinine levels. In the presence of impaired renal function, the total daily dose may be manipulated downwards in order to achieve satisfactory blood levels by adjusting the time interval between doses according to the patient's estimated creatinine clearance (ECC) using the equation:

$$\text{ECC} = \frac{(140 - \text{age [years]}) \times \text{weight [kg]} \times 1.23}{(\text{serum creatinine } [\mu\text{mol/L}])} \quad [9.1]$$

The ECC is multiplied by a correction factor of 0.85 for women. When the ECC is found to be reduced, the time interval between doses may be varied as follows [166]:

ECC, 80–90 mL/min: every 12 h  
 ECC, 50–80 mL/min: every 12–24 h  
 ECC, 10–50 mL/min: every 24–48 h  
 ECC, < 10 mL/min: every 48–72 h

Repeated calculations of the ECC may need to be made in a patient whose plasma creatinine is changing. Supplemental doses need to be given to patients on haemodialysis and further adjustments are needed in renal failure patients on continuous haemofiltration [167]. Alternative schedules exist that scale down the dose but continue administration every 8 or 12 h [156,168]. There are no studies comparing one regimen with another and either method may be used, although there are theoretical reasons for choosing the former since larger individual doses achieve higher peak levels with greater bactericidal effect.

#### *Once-daily dosage regimens*

Work in experimental animals and observations in patients suggest that once-daily dosing may be less likely to cause nephrotoxicity and ototoxicity, without the loss of bactericidal effect. This premise has received support from reports showing equal clinical efficacy with reduced nephrotoxicity in adults with severe infections who were treated with either a single daily dose or the equivalent dose given three times daily [169]. Similar conclusions were drawn in a group of 96 patients, in which elderly males predominated, when 4 mg/kg once daily was compared with 2 mg/kg 12-hourly [170]. However, in this study a correlation was found in the once-daily group between nephrotoxicity and an initial peak serum concentration exceeding 12 mg/L [170]. Although using different end-points, meta-analyses of the results of individual trials, which for the most part comprised relatively small numbers of patients with normal renal function and uncomplicated infections, have concluded that once-daily dosing appears to introduce no loss of efficacy in these groups and that overall it is neither more toxic nor less toxic to the kidneys than divided dosing [171,172].

It is conventional with once-daily regimens to infuse aminoglycoside intravenously in 100-mL diluent over 1 h rather than give it as a slow intravenous injection, in order to avoid any theoretical risk of neuromuscular blockade (see p. 214) [173]. This method of administration is acceptable in patients with uncomplicated lower respiratory tract infection in which susceptible organisms are suspected or have been demonstrated. Aminoglycosides have also been used successfully once daily in patients with cystic fibrosis, although there are few data concerning their efficacy and safety in this patient group [174]. There is also a relative paucity of data on once-daily aminoglycoside usage in patients with significant renal impairment, although most clinicians would find a substitute rather than use this class of drug at all in such circumstances without a pressing reason to the contrary.

#### *Blood levels with divided dose schedules*

A common convention with divided dose schedules is to check the peak serum level 1 h after a slow intravenous or intramuscular injection. The trough level should be estimated immediately before the next dose is due. Toxicity should be avoided if the peak level is kept below 10 mg/L and the trough level below 2 mg/L by manipulation of the length of time between doses (as above) and/or of the dose itself [166]. Dosage schedules and nomograms are intended for guidance only and should not be rigidly observed, as there is much pharmacokinetic variation in the handling of aminoglycosides between patients [175]. There is published work to suggest that patients with pneumonia due to Gram-negative bacilli do better if their peak serum levels of gentamicin (or tobramycin) exceed 7 mg/L, i.e. approach the toxic range [176]. High trough levels (>2 mg/L) are more important than high peaks with regard to the causation of toxic side-effects.

#### *Blood levels with once-daily dose schedules*

When once-daily dose schedules are used, each dose may be regarded as a loading dose. Peak serum levels are assumed to be high and need not be measured for clinical purposes. Similarly, trough levels at 24 h are low in the absence of significant renal impairment (ECC < 50 mL/min), so that measurement is also pointless. One approach is to use a fixed dose, such as 7 mg/kg (using ideal body weight if obese), of gentamicin or tobramycin and to determine whether the dose interval should be 24 h or longer by using a nomogram (Fig. 9.6), such as that validated at Hartford Hospital, Connecticut, using data from 2184 patients [177]. In such a case, the blood sample may be taken 6–14 h following the commencement of the infusion and the timing of the sample accurately recorded. Application of the nomogram tells the clinician whether to give the next dose in 24, 36 or 48 h or if the limits are

Fig. 9.6 Nomogram for once-daily gentamicin dosing. (Modified from Nicolau *et al.* [177] with permission.)

exceeded to ask for expert advice. Serum levels are thereafter monitored twice weekly, along with renal function using the plasma creatinine.

### *Tobramycin*

The routes of administration are as for gentamicin. Laboratory evidence exists to suggest that this aminoglycoside is more active than gentamicin against *Ps. aeruginosa* and less so against other Gram-negative bacteria such as *Serratia* spp. [178]. These *in vitro* findings do not appear to have produced any obvious differences between the two drugs in terms of clinical efficacy. It has been suggested that tobramycin is less likely to cause renal impairment and ototoxicity [179,180]. However, such claims have not been clearly translated into a measurable clinical advantage. A small study in patients with cystic fibrosis has suggested that 12-hourly intravenous dosing may be as effective and less toxic than conventional 8-hourly dosing [181].

The loading dose and usual dose range, as well as the peak and trough targets, are the same as those for gentamicin as outlined above [166], and the same induction and maintenance plans may also be used.

### *Netilmicin*

Netilmicin is very similar to gentamicin and tobramycin. The methods of administration, pharmacokinetics, dosage requirements and calculations are similar to those outlined for gentamicin. *In vitro* testing has shown it to be more active than gentamicin against some Gram-negative bacteria and less active for others such as *Ps. aeruginosa* [178] but these observations have not been translated into detectable clinical differences, nor indeed have claims, based on experimental work, that it is less toxic to the kidneys or ears [182]. The loading dose is the same as for gentamicin and tobramycin, as are the target peak and trough levels, a usual daily maintenance dose being 6 mg/kg [166].

### *Amikacin*

This compound, a derivative of kanamycin, is also available for intramuscular or intravenous use. At laboratory level it is less active than gentamicin, tobramycin and netilmicin against many of the Gram-negative bacillary organisms for which these drugs are used [178], but this can be compensated for by increasing the dose. However, amikacin has an important advantage over its three cousins in that it is unaffected by many of the aminoglycoside-inactivating enzymes to which gentamicin, tobramycin and netilmicin are susceptible. It is therefore at the very least a useful reserve drug when *in vitro* testing has shown resistance to these other drugs and some have advocated its routine use in place of gentamicin [183].

The dosage calculations require a loading dose of 7.5 mg/kg. Toxicity should be avoided by assaying peak and trough levels as outlined for gentamicin, peak levels being kept between 15 and 30 mg/L and the trough levels between 5 and 10 mg/L [166].

### *Nebulized aminoglycosides and other antimicrobial agents*

This method of administering antimicrobial agents [152] has mainly been used in patients with cystic fibrosis, whose lower respiratory tracts are known to be colonized by *Ps. aeruginosa*, the usual approach being to administer the drug on a regular basis to try to diminish the microbial load in order that the rate of decline in lung function might be reduced and to increase the time between exacerbations that might otherwise require hospital admission for parenteral therapy. A number of trials have been carried out, but because of their small size and varying methodology there has been lack of consensus and there are no good data on the optimal frequency of administration, e.g. continuous daily administration, short bursts, once, twice, three times daily, etc. Various antipseudomonal antimicrobial agents have been used in this manner, including colistin (a polymyxin), tobramycin, gentamicin, amikacin, carbenicillin, ticarcillin, azlocillin and ceftazidime, either alone or in combination [152,184]. Of the aminoglycosides, there is greatest experience with tobramycin [185,186]. A controlled trial using high-dose (600 mg three times daily) preservative-free tobramycin was shown to be effective in both controlling pseudomonal sputum load and improving forced expiratory volume in 1 s (FEV<sub>1</sub>) [187]. It is probable that lower doses may be effective and further studies are underway [185,186,188]. A meta-analysis of five controlled trials of nebulized antipseudomonal antimicrobial agents in cystic fibrosis claimed to show benefit in terms of reducing respiratory exacerbations and pseudomonal load and improving pulmonary function [184]. The disadvantages of this form of therapy are the inconvenience of administration, leading to reduced compliance, and its expense. Fears that this method of treatment might produce significant numbers of drug-resistant organisms do not appear to have been realized.

### **A polymyxin for respiratory use: colistin**

Colistin is a polymyxin that is not significantly absorbed from the gastrointestinal tract. Although available for intravenous use, its adverse effect profile has, up to now, limited its application by this route and its usually respiratory indication has been in nebulized form for the prophylactic control of *Ps. aeruginosa* infection between exacerbations in patients whose lower respiratory tracts are colonized by this organism, particularly those with cystic fibrosis [152]. The usual dose by this route is 1

megaunit (80 mg) twice daily after postural drainage has been performed, half this dose being recommended for patients who weigh less than 40 kg.

It has recently been suggested that reports of this drug's toxicity are exaggerated and claims have been made for its efficacy when used intravenously, either alone or in combination with a second antipseudomonal antibiotic, at a dose of 2 megaunits intravenously in 50 mL 0.9% saline over 30 min every 8 h in a trial of cystic fibrosis patients with *Ps. aeruginosa* infection [189].

The principal side-effects from its parenteral use are renal (acute renal failure) and neurological (perioral and peripheral paraesthesiae, vertigo, confusion, muscle weakness and respiratory impairment secondary to neuromuscular blockade), so that like aminoglycosides it is contraindicated in myasthenia gravis. The parenteral prescriber should monitor renal function with care and should also be alert for neurological symptoms. As with other antibiotics, wheezing may occasionally be produced when the more usual nebulized method of administration is used.

### Metronidazole in anaerobic infection

Metronidazole, a nitroimidazole, is one of the most important drugs currently available for the treatment of anaerobic infection and is also antiparasitic, being widely used for treating *Entamoeba* diarrhoea and giardiasis.

#### Mode of action

Metronidazole has a low molecular weight, which allows it to diffuse easily into bacteria. The drug, or one of its intermediate metabolites, appears to exert its bactericidal effect on anaerobic bacteria by interaction with DNA [190,191].

#### Spectrum of activity against respiratory pathogens

Metronidazole is highly active against virtually all Gram-negative anaerobic bacilli, including *Bacteroides fragilis*, which is commonly resistant to penicillin and one of the most frequently encountered pathogenic anaerobes [192,193]. It is also active against Gram-positive obligate anaerobic cocci and *Clostridium* spp. It has no useful activity against aerobic or microaerophilic organisms but resistant anaerobic organisms are unusual.

#### Administration, distribution and excretion

Metronidazole is well absorbed orally and diffuses readily throughout body water to the extent of penetrating not only pleural empyema fluid but also brain abscesses. Excellent blood levels can be achieved by this method of administration and there is no advantage in using

the expensive intravenous route if the drug can be swallowed. Absorption after rectal administration is reasonably good. Most of the drug is metabolized by the liver; about 15% of a dose being excreted unchanged in the urine, by which route the metabolic products are also removed. A small amount is excreted in the faeces. The serum half-life is approximately 8 h. This is unchanged in renal failure because of hepatic metabolism but may increase in liver disease, so that dose reduction in the presence of significant hepatic dysfunction may be necessary [194].

#### Dosage

The standard oral dose for anaerobic infection is 800 mg initially, then 400 mg 8-hourly. This gives comparable blood levels to the intravenous route for which a 15 mg/kg loading dose over 1 h followed by 7.5 mg/kg every 6–8 h is recommended [191]. The usual rectal dose is 1 g 8-hourly for 3 days, then 1 g 12-hourly. The duration of treatment depends upon the nature of the infection and its response. It may be necessary to treat a suppurative process such as an empyema for 2–4 weeks or even longer (see Chapter 14).

#### Adverse effects

Minor side-effects include the usual upper gastrointestinal disturbances that may be associated with many antibiotics, namely nausea, anorexia and vomiting. In addition, glossitis, a furred tongue and an unpleasant metallic taste may be recorded. The most serious side-effects are neurological and include ataxia, peripheral neuropathy, somnolence and seizures, so that the drug should be used cautiously in patients with a history of epilepsy. These are all rare but are potential risks if treatment is prolonged, if it involves high dosage or if there is associated liver disease. Other side-effects include reversible neutropenia and rarely pseudomembranous colitis, this being a somewhat paradoxical complication in a drug specifically used to treat this condition when caused by *Clostridium difficile* [195].

Drug interactions may result in the potentiation of warfarin via reduction of its hepatic metabolism. A disulfiram effect may occur with alcohol, which should therefore be avoided for the duration of metronidazole therapy.

There are no reports of teratogenicity but metronidazole crosses the placenta and common sense dictates that it should be avoided if possible during pregnancy, especially in the first trimester, as well as in nursing mothers unless a pressing need exists.

#### Principal uses in respiratory medicine

The main uses of metronidazole in respiratory medicine are in the treatment of aspiration pneumonitis (see Chapter 13) and other infections such as lung abscess or

empyema (see Chapters 14 & 15), in which anaerobic infection is likely. Such infection is often mixed and it is not recommended that metronidazole be used alone, as some anaerobic cocci and most microaerophilic streptococci (e.g. *Strep. milleri/intermedius*) are resistant. The addition of a second antimicrobial agent such as penicillin deals with these organisms. Thus the presence of microaerophilic streptococci or aerobes may cause treatment failures if metronidazole is used alone [196].

Other roles for metronidazole include the treatment of pseudomembranous colitis due to *Clostridium difficile* [195], in which its effect is comparable to that of vancomycin, and in thoracic complications of *Entamoeba histolytica* infection.

### Tinidazole

Tinidazole is a second nitroimidazole antimicrobial that is orally administered and that has a similar spectrum of activity and characteristics to metronidazole, except that it has a long half-life of 14 h, permitting a twice-daily dose of 500 mg–1 g after a loading dose of 2 g.

### Clindamycin

Clindamycin is the principal member of the lincosamide group of antibiotics, of which the parent compound lincomycin was derived from a soil *Streptomyces*. Lincomycin is not discussed further as it has been superseded by its derivative clindamycin, which has both greater antimicrobial activity and better absorption than the parent compound [197]. Clindamycin and related compounds act by binding to bacterial ribosomes and thus inhibiting protein synthesis. They are usually bacteriostatic but can act bactericidally.

#### Spectrum of activity against respiratory pathogens

The spectrum of clindamycin is, in some respects, similar to that of erythromycin, although it is not chemically related. It is active against *Strep. pneumoniae* and its good antistaphylococcal activity and penetrative properties are illustrated by its use in the treatment of osteomyelitis. However, it is inactive against *H. influenzae*, Gram-negative aerobes, *Mycoplasma pneumoniae* and the Legionellaceae. Clinically, it is most important for its effectiveness against Gram-positive and Gram-negative anaerobic bacteria, including *Bacteroides fragilis* [194], although a few resistant strains exist [192].

#### Administration, distribution and excretion

Clindamycin is well absorbed after oral administration, following which its serum half-life is about 3 h. A parenteral preparation for both intramuscular or intravenous

use also exists. It is well distributed to various tissues including lung and also penetrates the contents of abscesses, being actively transported into leucocytes [198–200]. The drug undergoes metabolism in the liver and is excreted into the gut via bile both unchanged and as metabolites and, to a lesser extent, in the urine. Dose modification may need to be made in the presence of significant hepatic or renal insufficiency.

#### Dosage

The oral dose range is 150–450 mg 6-hourly, a usual dose being 300 mg 6-hourly in the form of 150 mg capsules. An intravenous regimen of 600 mg 6-hourly or 800 mg 8-hourly is usual [201]. Dosage reduction may be necessary in hepatic or severe renal insufficiency.

#### Adverse effects

Diarrhoea occurring as a non-specific irritative effect may occur in about 20% of patients. It usually resolves promptly on withdrawal of the drug but should cause concern about the possibility of pseudomembranous (or antibiotic-associated) colitis, which is the most serious adverse effect of clindamycin. Pseudomembranous colitis may occur with virtually all antibiotics but is seen more frequently with clindamycin, which achieved notoriety as the first antibiotic to be linked with this complication, its reported incidence varying widely (according to diagnostic criteria) between less than 1% and 10% of cases [51,194,202]. The condition is characterized by the formation of yellow/white plaques or 'pseudomembranes' on the colonic mucosa and may be mild and self-limiting, although fatalities have occurred. It arises as a result of the production of cytotoxin by *Clostridium difficile*, an anaerobic organism that colonizes the bowel of about 3% of healthy adults. This organism is transmissible by the faecal–oral route and is resistant to many antibiotics including clindamycin but sensitive to vancomycin and metronidazole by mouth [51]. Treatment of antibiotic-associated diarrhoea is by prompt discontinuance of the antibiotic, hydration and the avoidance of antidiarrhoeal agents, which may result in toxic megacolon; metronidazole or vancomycin may be used if *C. difficile* and its toxin are demonstrated in the faeces. Some strains of *C. difficile* are non-toxicogenic.

Other adverse effects include skin rashes, which occur in 3–5% of cases; hepatic dysfunction, as indicated by a transient elevation of transaminase levels; and haematological abnormalities, indicated by neutropenia or thrombocytopenia. Anaphylactic reactions are rare.

#### Principal uses in respiratory medicine

The widespread use of clindamycin has been curtailed by

fears about its propensity to cause pseudomembranous colitis, so that its use is reserved for serious infections. Its main application in respiratory medicine is in the treatment of anaerobic infection, e.g. aspiration pneumonia/lung abscess, particularly when these have arisen in the community. Many physicians would use benzylpenicillin as the drug of first choice, possibly supplemented by metronidazole, before falling back on clindamycin if the patient fails to respond. Clindamycin has a clear role in such infection when the patient is known to be allergic to penicillin and some would use it as a drug of first choice in seriously ill patients. The use of clindamycin in these circumstances is supported by some trial work that has suggested its superiority to penicillin in anaerobic pulmonary infection [203,204].

Clindamycin has also been used as an oral therapy in combination with primaquine (see below) for AIDS patients with mild to moderate PCP as an alternative to co-trimoxazole.

## Glycopeptide antibiotics and MRSA

### Vancomycin

Vancomycin is a high molecular weight glycopeptide produced using a *Streptomyces* originally recovered from a Borneo jungle soil sample that was found to *vanquish* staphylococci, hence the name. It has its action by interfering with both cell wall and RNA synthesis. It has been available since the 1950s and is the original member of its class, the appearance of early samples earning them the sobriquet of 'Mississippi mud'. Teicoplanin is the most recent member of this class to become generally available. Were it not for the toxicity of vancomycin, it might well have been the drug of choice for serious staphylococcal infections; indeed the fact that its use has been limited by its toxicity is probably one reason why it remains effective. However, it has undergone a revival both with the emergence of staphylococci resistant to semisynthetic penicillins, especially MRSA, and with the recognition of antibiotic-associated pseudomembranous colitis caused by toxins from *Clostridium difficile* [51,205].

### Spectrum of activity against respiratory pathogens

Vancomycin is a relatively narrow spectrum agent that is bactericidal against Gram-positive cocci including *Staph. aureus* and *Staph. epidermidis*. MRSA are ordinarily sensitive but the emergence of vancomycin-resistant enterococci is a major concern because the plasmid-mediated transfer of enterococcal resistance to other genera such as staphylococci is a real possibility that could lead to untreatable systemic staphylococcal infection [12,83,206]. Indeed a few reports of *Staph. aureus* with reduced vancomycin susceptibility (MIC  $\geq 8\mu\text{g/mL}$ ) have recently

been documented in North America and Japan [207–209], these organisms having also been referred to as vancomycin-insensitive MRSA. As with *Staph. aureus*, so *Staph. epidermidis* and other coagulase-negative staphylococci are increasingly resistant to methicillin, which is relevant to general medical practice as they may colonize plastic catheters and cannulae and use them as stepping stones to infection of prosthetic and, uncommonly, native heart valves. Although these organisms are ordinarily sensitive to vancomycin, a resistant coagulase-negative *Staphylococcus* was first documented over 10 years ago [210]. Of other Gram-positive cocci, *Strep. pneumoniae* (including penicillin-resistant forms) and *Strep. pyogenes* are also sensitive to vancomycin. Streptococci of the viridans group and non-respiratory streptococci may require the addition of an aminoglycoside to achieve a bactericidal effect. Many anaerobic organisms, including *Clostridium difficile*, are sensitive. Vancomycin is ineffective against Gram-negative respiratory pathogens [211].

### Administration, distribution and excretion

There is no therapeutically significant absorption from the gut and oral administration is confined to the treatment of *Clostridium difficile*-associated colitis. Intramuscular injection is particularly painful and the intravenous route is therefore used for parenteral administration. Adequate levels have been found in pleural fluid following parenteral administration [212]. The drug is excreted largely unchanged by the kidneys and in the presence of normal renal function the plasma half-life is about 6 h.

### Dosage

A parenteral loading dose of 750 mg to 1 g (15 mg/kg) is recommended. An average dose thereafter would be 500 mg infused over 1 h every 6 h although, in view of its half-life, 1 g may be given 12-hourly over 100 min as an alternative. Particular care has to be paid to dosage because of the potential for serious side-effects, especially ototoxicity. Peak plasma levels should not exceed 30–40  $\mu\text{g/mL}$  and 60–80  $\mu\text{g/mL}$  is within the toxic range [211]. Maintenance dosage in renal insufficiency may be estimated from the formula:

$$\text{Vancomycin dose (mg) per 24 h} = 150 + (15 \times \text{creatinine clearance [mL/min]}) \quad [9.2]$$

Creatinine clearance may be estimated using Eqn 9.1 on p. 214. Alternatively vancomycin dose in patients with renal insufficiency may be predicted using a nomogram [213]. Blood levels of vancomycin may be monitored during parenteral treatment, although the value of this practice has been questioned [214]. Samples should be taken immediately before and 2 h after completion of the

infusion. In general, such assays may be made after the third or fourth dose and subsequently at least twice weekly. Typical target ranges are 5–10 µg/mL for the trough level and 20–30 µg/mL for the peak level, leaning towards the lower end of the range in patients with renal insufficiency. As with aminoglycosides, an alternative to reducing the dose is to increase the length of time between doses.

The oral dose for *Clostridium difficile* colitis is 125 mg 6-hourly for 7–10 days.

#### *Adverse effects*

The most serious side-effect is deafness due to eighth cranial nerve damage. This can be permanent and is sometimes preceded by tinnitus, which can be taken as an indication to discontinue the drug. Nephrotoxicity may also occur but is less common, having been a problem with earlier relatively impure preparations of 'Mississippi mud'. Both these side-effects may be avoided by careful dosing and observance of plasma levels (see above). It should be noted that patients who are in renal failure may attain toxic levels of vancomycin when the drug has been administered orally for the treatment of *Clostridium difficile* colitis [215]. The likelihood of ototoxicity and nephrotoxicity may be increased by concurrent aminoglycoside therapy which, if used, should be attended by a dosage limitation of vancomycin to 0.5 g every 8 h [216].

Other adverse effects include rashes, fever and local thrombophlebitis. Extravasation of the drug may cause local tissue necrosis. Alarming flushing of the face and trunk may occur ('red man syndrome') if intravenous doses are given rapidly, hence the recommendation for a slow infusion rate. This is caused by histamine release and has been associated with hypotension and collapse. Febrile reactions and reversible neutropenia are described.

#### *Principal uses in respiratory medicine*

Vancomycin is reserved for use in serious infections because of its potential toxicity. It is widely used in the treatment of MRSA infections and may also be used in patients with serious *Staph. aureus* infections who cannot take penicillin derivatives because of allergy.

Oral vancomycin is the drug of choice in ill patients with antibiotic-induced pseudomembranous colitis, metronidazole being an inexpensive preparation that may be used as an alternative in a less sick patient.

#### *Teicoplanin*

Teicoplanin is a more recent high molecular weight glycopeptide complex, produced by an *Actinomyces*. It is chemically similar to vancomycin but more lipophilic,

having good intracellular penetration. It has a similar spectrum of activity to vancomycin, has a less troublesome adverse effect profile but is more costly. Its pharmacokinetics permit once-daily intravenous injection. Unlike vancomycin, it may be given intramuscularly without excessive pain and absorption by this route is equivalent to intravenous injection. There is no oral formulation.

#### *Spectrum of activity against respiratory pathogens*

The antimicrobial activity of teicoplanin is broadly similar to that of vancomycin. It too has excellent activity against *Staph. aureus*, including MRSA. Its combination with an aminoglycoside may produce a synergistic effect against *Staph. aureus* and this is usual in endocarditis. There is some variability between teicoplanin and vancomycin with regard to coagulase-negative staphylococci and enterococci, some organisms of either class being resistant to one and sensitive to the other [217].

#### *Administration, distribution and excretion*

Peak serum concentrations occur 30 min after intravenous, and 4 h after intramuscular, injection. The drug is widely distributed and largely excreted unchanged by the kidneys. It has a long elimination half-life of about 1 week [217]. This is increased in renal insufficiency, necessitating either dose reduction or an increase in time between doses.

#### *Dosage*

Three loading doses of 400 mg (about 6 mg/kg) 12-hourly by intravenous bolus or 30-min infusion are recommended for severe infection, followed by 400 mg once daily either intravenously or intramuscularly. This is likely to achieve a desirable trough level of greater than 10 mg/L. It is not usually necessary to monitor blood levels of teicoplanin as this drug is less likely to be associated with significant adverse effects. Such monitoring may be required when treating endocarditis, in which case dose adjustment up to 800 mg in order to achieve trough levels of greater than 20 mg/L may be necessary.

#### *Adverse effects*

Side-effects include rashes, fever and local thrombophlebitis but these are uncommon. Ototoxicity and altered renal function are both unusual, occurring in 0.3 and 0.6% of patients respectively [217]. Impairment of renal function is seen less commonly when teicoplanin is administered with an aminoglycoside than when vancomycin is used in a similar combined fashion. Anaphylactoid reactions with histamine release ('red man syndrome', see above) appear to be rare. They may, but

need not necessarily, occur following substitution of teicoplanin for vancomycin. Leucopenia, thrombocytopenia and eosinophilia are described.

#### *Principal uses in respiratory medicine*

Teicoplanin has similar indications to vancomycin and experience with its use is increasing. Its once-daily dosage and relative freedom from adverse effects, particularly ototoxicity and nephrotoxicity, when administered with an aminoglycoside are relative advantages. It has therefore been advocated as a secondary agent that may be added to a  $\beta$ -lactam/aminoglycoside combination if fever fails to resolve in the neutropenic bacteraemic patient. Whether the emergence of staphylococcal resistance will be a greater problem for teicoplanin than vancomycin remains to be seen.

There is no oral preparation of teicoplanin and oral vancomycin remains the drug of choice in ill patients with antibiotic-induced pseudomembranous colitis (see above).

### **Pentamidine and *Pneumocystis carinii* pneumonia**

Pentamidine isethionate is an antiparasitic agent that has been used for over 50 years in the treatment of African trypanosomiasis (sleeping sickness) and leishmaniasis (kala-azar). It was found to be effective against *Pneumocystis carinii* in the 1950s, and PCP is the only respiratory application for this drug. Its use increased both as a result of the AIDS epidemic and the growth of immunosuppressant therapy in medicine. For an account of the clinical management of PCP the reader is referred to Chapter 52.

#### *Mode of action, administration and pharmacokinetics*

Pentamidine is a diamidine, the precise antimicrobial actions of which are incompletely understood, although the inhibition of folate metabolism, glycolysis and nucleic acid synthesis have been proposed as possible mechanisms [218,219].

Pentamidine is not absorbed following oral administration. It may be given intravenously (see Adverse effects), intramuscularly or, in certain circumstances, as a nebulized solution. Although well absorbed following intramuscular injection, plasma levels are low and it is thought that the drug is taken up by tissues. It may be partially metabolized by the liver and excretion, which is principally renal, is slow so that the drug may be detected in the urine for several weeks [220,221].

#### *Dosage*

When pentamidine has to be used in the treatment of PCP,

it is recommended that it should be given as a single intravenous dose of 3–4 mg/kg daily [219]. Caution is advised in administering pentamidine to patients with renal insufficiency because the drug is known to have nephrotoxic properties and it has a tendency to accumulate. If the creatinine clearance is 10–50 mL/min, the dosage interval should be prolonged to 36 h, and at a level of less than 10 mL/min to 48 h [222]. The usual course of treatment lasts for 14 days, although this may need to be prolonged to 3 weeks in patients with AIDS [223]. It was usual to give pentamidine by deep intramuscular injection but it is now customary to give the drug intravenously, provided that it is given by slow infusion in about 100 mL 5% dextrose over 60–120 min in order to reduce side-effects.

Aerosolized pentamidine may be given as PCP prophylaxis at a dose of 300 mg once a month or 150 mg every 2 weeks and is dispensed as a ready-to-use solution [224]. Prior treatment with a bronchodilator is advised (see Adverse effects). The type of jet nebulizer and the flow rate used may be important in achieving adequate lung deposition, as the optimal particle size for alveolar deposition is 1–2  $\mu$ m. Systems such as Respigard ii (Marquest), driven by air (or oxygen) at a flow rate of 6 L/min, have been validated for this purpose [225].

#### *Adverse effects*

Side-effects (Table 9.5) are a particular problem with parenteral pentamidine therapy and are experienced by almost 50% of patients receiving this form of therapy [226]. Immediate effects may take the form of severe hypotension, with associated sweating, dizziness, syncope and dyspnoea [227]. These reactions may occur in about 5% of patients after intramuscular injection and in about 75% after *rapid* intravenous injection. Fatal reactions have been recorded in children. In addition, there may be associated nausea, vomiting and itching. Such effects may last for 30 min and do not require cessation of therapy but clearly the patient should be forewarned about them. The greater incidence of these effects with intravenous injection led to the recommendation that the intramuscular route should be used, although further evidence suggests that this recommendation may be inappropriate provided that the drug is infused over 1 h [227]. Intramuscular administration is painful and local abscess formation at the injection site is well described. The anterior aspect of the thigh is preferred in order to reduce the possibility of faecal contamination of an ulcerated gluteal injection site.

The most important limiting side-effect is nephrotoxicity [226]. This occurs in about one-quarter of patients receiving pentamidine and although usually mild and reversible it necessitates discontinuance of the drug as it has been implicated in reported fatalities. Alternate-day plasma creatinine estimations are advised during the

**Table 9.5** Adverse effects of parenteral pentamidine.

Local abscess formation

course of treatment. Careful consideration should be given before the concurrent addition of other potentially nephrotoxic drugs, such as aminoglycosides, foscarnet and amphotericin B, as rapidly progressive renal failure may follow [228].

Other adverse effects include hypoglycaemia [229], which occurs as a result of inappropriately high insulin levels, and is followed within days, in some cases, by diabetes mellitus. These effects result from the toxic effects of pentamidine on the  $\beta$  cells in the pancreatic islets [218], and requires blood glucose monitoring for early detection. Pancreatitis may also occur [230]. Hypocalcaemia has been described but is uncommon. Other electrolytic abnormalities include hyperkalaemia and hypomagnesaemia. Haematological abnormalities are unusual and include anaemia, neutropenia and thrombocytopenia [218]. Abnormal liver function may be reflected by raised transaminases [229]. QT interval prolongation may occur on the ECG and torsades de pointes or other dysrhythmias may arise. Cutaneous rashes may also occur.

Aerosolized pentamidine is free from systemic side-effects as little of it is absorbed. It has a propensity to induce wheezing in susceptible subjects and this may be countered by prior treatment with a nebulized bronchodilator [231,232]. The patient may complain of an unpleasant metallic taste as indeed may also be the case with parenteral administration.

#### *Principal uses in respiratory medicine*

The only therapeutic indication for pentamidine therapy in respiratory medicine is the treatment of PCP [220]. It is mainly used as second-line therapy in patients who are failing to respond to treatment with high-dose co-trimoxazole after 4–5 days or in those patients in whom co-trimoxazole has to be discontinued because of its own adverse

effects. Co-trimoxazole is generally considered more efficacious, both treatments having a high incidence of side-effects.

Aerosolized pentamidine has been used as a daily single dose for 3 weeks to treat patients with PCP in which the infection was classed as mild or moderate ( $PO_2 > 8$  kPa, 60 mmHg) but this approach has proved less effective than the conventional intravenous route [220]. This route of administration is more commonly used as a monthly prophylactic dose in patients who cannot tolerate prophylactic co-trimoxazole because of cutaneous allergy or other adverse effects.

### **Antimicrobial agents, other than co-trimoxazole and pentamidine, used for treating PCP**

#### *Trimetrexate/folinic acid*

Trimetrexate is a lipid-soluble antifolate and, like trimethoprim and methotrexate, is an inhibitor of dihydrofolate reductase although it is much more potent in this regard than trimethoprim. It was developed as a myelosuppressive agent and has its antiparasitic effect by preventing *Pneumocystis carinii* from synthesizing folate. Trimetrexate must be supplemented with calcium folinate (leucovorin) in order to prevent or reduce myelosuppression and mucosal ulceration, as well as hepatic and renal dysfunction. The microbe itself is unable to take up this supplement as it lacks a folate transport system [233]. Trimetrexate may be given by once-daily intravenous infusion at a dose of 45 mg/m<sup>2</sup> for 3 weeks, calcium folinate being given at a dose of 20 mg/m<sup>2</sup> 6-hourly orally or by slow intravenous injection (at a separate site) for 3 days longer. Nausea, rashes and a peripheral neuropathy may also occur. This drug has been found to be effective in the treatment of moderate to severe PCP ( $PO_2 < 8$  kPa, 60 mmHg), although less so than co-trimoxazole. It is as well or better tolerated [234]. Some experts have used trimetrexate alone or in combination with dapsone (see below) as a second-line treatment, in preference to the more toxic pentamidine, for patients who are intolerant of co-trimoxazole or in whom this drug has failed [220].

#### *Atovaquone*

Atovaquone is a member of a group of antiprotozoal agents (hydroxynaphthoquinones) and has been found to be effective in the treatment of PCP. It probably has its effect by inhibiting nucleic acid and ATP synthesis. It is administered orally and has a low bioavailability, its absorption being increased significantly if it is taken with food, especially if this is fatty. It is predominantly excreted unchanged in the faeces. The dose is 750 mg taken as three

250-mg tablets once daily with food. An oral suspension may provide better bioavailability. The principal side-effect that limits its use is diarrhoea, since absorption may be further impaired with subsequent treatment failure. Nausea and rashes may also occur. Atovaquone has been used as an effective secondary substitute for co-trimoxazole and combinations such as dapsone/trimethoprim and clindamycin/primaquine in the treatment of mild to moderate cases of PCP ( $PO_2 > 8$  kPa, 60 mmHg) when these agents cannot be tolerated [220].

#### **Dapsone/trimethoprim**

Dapsone is an orally administered antileprotic drug also used in malaria prophylaxis. It belongs to the sulphone group and may also be effective in the treatment of PCP when used in combination with other drugs. It has its effect by inhibiting folate metabolism. It is well absorbed from the gut and is mainly metabolized by the liver. Haematological side-effects include haemolytic anaemia, leucopenia and methaemoglobinemia. Drug rashes are common. Hepatic reactions and fever may also occur. Eosinophilic pneumonia has occurred. Dapsone has been found to have a high failure rate when used singly to treat PCP of mild to moderate severity ( $PO_2 > 8$  kPa, 60 mmHg) and this has led to its use in an orally administered regimen with trimethoprim (dapsone 100 mg daily as one dose, trimethoprim 20 mg/kg daily in two to four divided doses). There are some data suggesting that this combination appears to be of approximately equal efficacy to orally administered co-trimoxazole and clindamycin/primaquine but with fewer adverse effects [129,220].

#### **Clindamycin/primaquine**

The lincosamide antibiotic clindamycin has been described above and is best known in respiratory practice for its activity against anaerobes. Another respiratory use of clindamycin is for the treatment of mild to moderate PCP in conjunction with the antimalarial primaquine, the main side-effect of which is haemolysis in patients with glucose 6-phosphate dehydrogenase deficiency, which should be excluded before its use in those with coloured skins. One such regimen comprised clindamycin 600 mg three times daily orally and primaquine 30 mg base as a single daily dose [235].

### **Antibiotics used in tuberculosis and opportunistic mycobacterial disease**

The preferred antituberculous drugs are rifampicin, isoniazid, pyrazinamide and ethambutol. Less commonly used drugs include rifabutin, streptomycin, newer macrolides such as clarithromycin and azithromycin, quinolones such

as ciprofloxacin and ofloxacin, cycloserine, prothionamide (not marketed in the UK), capreomycin, kanamycin and amikacin.

The management of tuberculous and non-tuberculous (opportunistic) mycobacterial disease is described in Chapters 19 and 20 and is not discussed in detail here. The respiratory applications of the aminoglycosides (see above) are almost entirely non-tuberculous, although streptomycin and amikacin have a secondary role in tuberculous and opportunistic mycobacterial disease. Rifabutin, a newer rifamycin, is now licensed for use as prophylaxis against *Mycobacterium avium-intracellulare* complex infections in patients with a low CD4 count, as well as for the treatment of non-tuberculous mycobacterial disease and tuberculosis. A role is emerging for the newer macrolides (see above) in the management of non-tuberculous mycobacterial disease, particularly *M. avium-intracellulare* complex. A description of rifampicin with reference to its non-tuberculous applications in respiratory medicine follows.

#### **Rifampicin**

Rifampicin (USA, rifampin) is a semisynthetic derivative of one of the rifamycin antibiotics produced by a *Streptomyces*, being the most active of those so far investigated, although rifabutin (see below) shows better activity against the *M. avium-intracellulare* complex group of organisms. It is bactericidal by virtue of its inhibition of DNA-dependent RNA polymerase.

#### *Spectrum of activity against respiratory pathogens*

In addition to its antimycobacterial properties (see Chapters 19 & 20), rifampicin is active when used to treat a wide range of other bacteria including both coagulase-positive and coagulase-negative staphylococci, against which it is very effective. It also has the greatest *in vitro* potency of any known antibiotic against *Legionella pneumophila*; *Legionella micdadei* is also sensitive. It is effective against *H. influenzae* and also active against streptococci, but less so than penicillins and its activity against most Gram-negative aerobic bacilli tends to be lower than that of the aminoglycosides. It is active against the opportunist pathogen *Rhodococcus* (formerly *Corynebacterium*) *equi*, a variably acid-fast Gram-positive bacillus that may cause lung abscesses and progressively cavitating pneumonia in immunosuppressed patients, especially those with AIDS.

As is the case with mycobacteria, many large bacterial populations may contain mutant organisms that are resistant to rifampicin. It is therefore a general rule that rifampicin should never be given alone (except for short-term meningococcal prophylaxis among contacts) and

that it should be supported by another antibiotic to which the organisms in question are likely to be sensitive.

#### *Administration, distribution and excretion*

Rifampicin is very well absorbed from an empty stomach after oral administration and reaches effective concentrations in the lungs and other tissues, as well as in abscess cavities and pleural exudates. Hepatic metabolism occurs and both unchanged rifampicin and its metabolites are secreted in bile. Unmetabolized rifampicin is reabsorbed from the gut and the process repeated; the metabolites are excreted in the faeces. This excretion accounts for about two-thirds of a dose, the remainder being excreted in the urine where it can be usefully detected by qualitative assay or visually, by virtue of its orange-reddish colour, in order to check patient compliance. The plasma half-life is about 5 h [236], although a therapeutic level may be maintained for 12 h or more, partly due to the enterohepatic circulation referred to above. No dosage modification is necessary in renal failure because of clearance through the liver but it should be avoided or used with extra care in the presence of hepatic insufficiency. Rifampicin may also be given intravenously as a brilliant orange-coloured infusion, although this route probably offers no advantage, other than brightening up the ward, unless the patient is unable to take oral medication.

#### *Dosage*

The usual adult dosage of rifampicin in tuberculosis is 600 mg daily for patients who weigh 50 kg or more and 450 mg daily for those below this weight. These doses are well tolerated but whether they are ideal for other forms of infection is not known. The same single dose may be given by infusion over 2 h in a tuberculous patient who cannot swallow. If rifampicin is used parenterally with a macrolide to treat serious *Legionella* infection, it is conventional to administer the drug at a total dose of 600–1200 mg daily, split 12-hourly.

#### *Adverse effects and interactions*

These have been discussed in Chapter 19. The effect of rifampicin as an inducer of liver and intestinal microsomal enzymes is particularly important when it is used in asthmatic patients who require systemic corticosteroid therapy. These patients are likely to experience a significant deterioration in their asthma when rifampicin is started unless the dose of corticosteroid is increased [237]. Similar deterioration in the condition of patients with other disease controlled by corticosteroids may well occur. Similar reductions in the serum concentrations of many other drugs may occur if they are used concurrently, including diltiazem and other antidysrhythmic

agents, fluconazole and other antifungal antibiotics, phenytoin, warfarin, cyclosporin, azathioprine, theophylline, thyroxine, chlorpropamide and other sulphonylureas, atovaquone and oral contraceptives. It behoves the prescriber of rifampicin to check for potential interactions against any other drug that the patient might happen to be taking. The capacity of rifampicin to induce liver enzymes may produce adrenal crisis within 2 weeks of the onset of treatment by increasing the oxidation of endogenous cortisol in patients with pre-existing adrenal insufficiency, such as may occasionally occur in patients with tuberculosis [238]. As with isoniazid and pyrazinamide, hepatic reactions, which have rarely been fatal, may occur with rifampicin; thus it is recommended that liver function tests should be checked before commencement of therapy and if abnormal should be repeated during treatment, if the patient develops symptoms or signs of hepatitis or if they become generally unwell during the course, so that they may be withdrawn promptly if clinically significant hepatic abnormalities occur [239].

#### *Principal uses in respiratory medicine*

The place of rifampicin in respiratory diseases other than tuberculosis is not clear-cut. It is not a first-line drug in the management of serious staphylococcal infection, but reports of its successful use in combination with vancomycin to increase serum bactericidal activity in patients with MRSA endocarditis [240] suggest that its role in the management of MRSA infections may merit further investigation. If serious MRSA infection does not respond to vancomycin or teicoplanin alone, then the addition of an aminoglycoside such as gentamicin and rifampicin may be justifiable [240]. Caution should be exercised before assuming that such combinations will be beneficial, as some studies have indicated that antagonism between rifampicin and other antibiotics may occasionally occur [241,242]. When any such combination is used in clinical practice, its efficacy should ideally be tested in the laboratory by the measurement of serum bactericidal activity.

Rifampicin has also been proposed as a second antibiotic for use in combination with a macrolide in the treatment of severe cases of Legionnaires' disease [243] (see Chapter 13).

#### *Rifabutin*

Rifabutin is another bactericidal rifamycin that has become available more recently than rifampicin. It is administered orally and has broadly similar pharmacokinetics. It has no advantages over rifampicin in the treatment of tuberculosis, although rifampicin-resistant strains may sometimes be susceptible to rifabutin [244]. However, it does show greater activity than rifampicin against

organisms of the *M. avium-intracellulare* complex and is usually used at a dose of 300–600 mg daily as a single dose in combination with other drugs such as clarithromycin (see p. 205) and ethambutol. Higher doses of rifabutin have a propensity to produce uveitis and particular care has to be taken in this regard when it is used together with clarithromycin, fluconazole or ritonavir (and other HIV protease inhibitors). It may be used singly at a dose of 300 mg daily as prophylaxis against disseminated *M. avium-intracellulare* complex infection in patients with AIDS, when the CD4 T-lymphocyte count falls to  $<0.1 \times 10^6/L$ , and has been shown to significantly reduce the frequency of this important complication that contributes significantly to the morbidity and mortality of this group of patients [245].

### Sodium fusidate (fusidic acid)

Sodium fusidate is a salt of fusidic acid that was isolated from a strain of the fungus *Fusidium coccineum*. It is an antibiotic of relatively low toxicity and with a narrow band of activity, being most effective against *Staph. aureus* and *Staph. epidermidis*, including some strains resistant to penicillin derivatives such as methicillin. It is relatively ineffective against other common respiratory pathogens and staphylococcal infection is virtually the only indication for its use.

Its mode of action involves the inhibition of bacterial protein synthesis, with either bacteriostatic or bactericidal effects. Fusidic acid-resistant strains of *Staph. aureus* have been noted to emerge readily *in vitro* and the development of clinical resistance during treatment has also been reported [246]. This has led to a tendency for fusidate to be used with another agent such as an antistaphylococcal penicillin and, despite laboratory reports of antagonism with such combinations, this may produce satisfactory clinical results [247].

Fusidate is very well absorbed orally and there seems to be little point in using the parenteral route if the more natural route is available [248]. A topical ocular preparation has been proposed as a less toxic alternative to chloramphenicol [249]. The drug is well distributed and its metabolic products are secreted in bile, urinary secretion being minimal, so that dosage modification in renal failure is unnecessary [250]. When oral administration proves impossible, the drug may be given intravenously as diethanolamine fusidate. The dose of sodium fusidate is 500 mg 8-hourly, with up to 3 g daily in severe infection. The usual intravenous dose is 500 mg given by slow infusion three times daily.

Adverse effects include mild gastrointestinal tract disturbance, rashes and venospasm followed by thrombophlebitis, especially if infusion has been too rapid. Reversible abnormalities of liver function may occur, particularly with the parenteral route, as may clinical

jaundice which necessitates discontinuance of the drug [251].

Clinical confidence in the use of fusidate as a single antistaphylococcal agent is somewhat thin. However, it is frequently used in a supporting role, despite some laboratory reservations about a possible antagonistic effect against penicillins. It is not commercially available for use in the USA.

### Fluoroquinolones

Ciprofloxacin was the first of the fluoroquinolone antimicrobials to become available in the UK [252]. These drugs are related to, but considerably more potent than, the early antiseptic quinolone group of which nalidixic acid is a familiar member, this increased potency having been achieved by various modifications to the basic dual ring structure, including the addition of fluorine and piperazinyl substituents. Ofloxacin and its optical isomer levofloxacin are also available in the UK, as is grepafloxacin. Fluoroquinolones currently under development or not available in the UK include lomefloxacin (available in the USA), sparfloxacin (available in the USA), cinafloxacin and others. This group of drugs is bactericidal and has a broad spectrum, with excellent activity against Gram-negative bacteria, including *H. influenzae*, *Moraxella catarrhalis*, Enterobacteriaceae and *Pseudomonas* spp. They are effective against *Staph. aureus* but on the whole have more modest activity against streptococci, although this is likely to be improved with some of the more recent compounds such as levofloxacin, cinafloxacin and grepafloxacin. Their activity against anaerobes, including *Bacteroides fragilis*, is minimal. Temafloxacin was withdrawn worldwide by the manufacturer in 1992 soon after its launch because of a much higher rate of serious adverse reactions (hypoglycaemia, haemolytic anaemia, renal failure, coagulation defects, anaphylaxis and death) than had been seen with previous quinolones. One result of this is that all new drugs belonging to this class are subject to intense scrutiny and a long gestational period before their release.

### Ciprofloxacin

#### Mode of action

The mode of action of ciprofloxacin and other quinolones is primarily by inhibition of a bacterial enzyme, DNA gyrase, which is essential in the process of bacterial DNA replication and other cellular processes [253].

#### Spectrum of activity against respiratory pathogens

Ciprofloxacin has an unusually broad spectrum of activity, being effective *in vitro* against those Gram-negative

organisms associated with hospital-acquired pneumonia, including the Gram-negative enteric bacilli such as *Enterobacter* spp., *E. coli* and *Serratia*, *Klebsiella* and *Proteus* spp., as well as more highly resistant organisms such as *Ps. aeruginosa* and *Acinetobacter* spp. It is also highly effective against *H. influenzae* and *Moraxella catarrhalis* [254]. It is active against methicillin-sensitive *Staph. aureus* but less so against *Strep. pneumoniae*, the commonest causal organism in community-acquired pneumonia. Most strains of MRSA are resistant. It has no useful activity against anaerobes. 'Atypical' causes of pneumonia, such as *Mycoplasma pneumoniae*, *Legionella* spp. and *Chlamydia* spp., may be susceptible to ciprofloxacin and other 4-quinolones but data concerning clinical effectiveness in this area are unsurprisingly thin, with an absence of comparative trials with first-line drugs [255–257]. Ciprofloxacin may be active *in vitro* against *Mycobacterium tuberculosis* as well as some opportunistic mycobacteria including *M. kansasii* but its activity against the *M. avium-intracellulare* complex is poor.

As with all antimicrobial agents, the emergence of resistant organisms is likely to become an increasing problem [258,259]. It is not uncommon to isolate resistant strains of *Ps. aeruginosa* in patients whose lower respiratory tracts are colonized by these organisms when they have received repeated courses of treatment with ciprofloxacin for infective exacerbations. Resistance among Enterobacteriaceae has also been reported when this drug has been used prophylactically in neutropenic patients [253].

#### *Administration, distribution and excretion*

The absorption of ciprofloxacin after oral administration, although incomplete, is adequate to permit this route to be used effectively, peak serum levels being reached at 90 min with a half-life of about 4 h. Its absorption from the gut is much reduced by the simultaneous administration of cationic compounds, including aluminium- or magnesium-containing antacids, calcium and iron salts and enteral tube feeds [253]. The drug penetrates the lung well. Ciprofloxacin is excreted in the urine both unchanged and, to a small extent, as its metabolites. Dosage reduction in significant renal insufficiency (ECC <30 mL/min) may be achieved by once-daily administration. Ciprofloxacin may also be given by intravenous infusion.

#### *Dosage*

The usual oral dosage is 500–750 mg twice daily. It is probable that the higher dose should be used in treating pseudomonal infection by this route. The intravenous dose is 200–400 mg twice daily, infused over 30–60 min to minimize venous irritation.

#### *Adverse effects and interactions*

The most common side-effects are minor gastrointestinal tract upsets, serious adverse reactions being rare [260], although this statement is subject to review as experience with the drug increases. Antibiotic-related *Clostridium difficile* colitis is rare, possibly because of the drug's minimal disturbance of bowel anaerobes [261]. Central nervous system (CNS) effects may occur and include headache, dizziness, restlessness, sleep disturbance and tremors. The quinolone group of antibiotics have an epileptogenic potential, so that they should be used with caution in patients with a history of seizures, particularly if used in combination with theophylline. This potential may be enhanced by an interaction with non-steroidal anti-inflammatory drugs [262]. Hepatic reactions, Achilles tendonitis/rupture and photosensitivity are rare [261]. Ciprofloxacin inhibits cytochrome P450 and therefore the metabolism of theophylline, the plasma level of which may be substantially increased so that levels should be monitored; in this situation it is recommended that the usual dose of theophylline is halved [263]. Warfarin may be potentiated. Rashes in general are uncommon and vasculitis rare [264]. Its use in growing children is discouraged by the potential risk of damage to articular cartilage that has been observed in experimental animals following quinolone therapy [260], although its use may be justified in appropriate circumstances such as in exacerbations of *Ps. aeruginosa* infection in adolescent children with cystic fibrosis [261]. Arthralgia occasionally occurs in this situation [253]. Haemolytic anaemia, renal impairment, hypoglycaemia and anaphylaxis are all rare side-effects of quinolones but have been reported [265].

#### *Principal uses in respiratory medicine*

Ciprofloxacin and other quinolones currently under laboratory or clinical evaluation have a useful place in the management of difficult respiratory infections, particularly in hospital-acquired pneumonia where infection with Gram-negative enteric bacilli is likely. The empirical use of ciprofloxacin as a first-line agent for the treatment of community-acquired respiratory infections, both in hospital and in the community, remains inadvisable in view of the ready availability of safe narrower-spectrum alternatives that are more effective against *Strep. pneumoniae*. It is notable that pneumococcal bacteraemia has occurred in some patients during treatment with ciprofloxacin [266]. Ciprofloxacin may be an entirely appropriate second-line choice in patients with COPD whose infective exacerbations have failed to respond to a penicillin, in which case the problem may be resistant *H. influenzae* or *Moraxella catarrhalis*, both of which are susceptible to ciprofloxacin. Although the availability of oral antipseudomonal agents has obvious attractions, the clinical response to medica-

tion via this route in patients whose lower respiratory tracts are permanently colonized by large numbers of these organisms and who experience exacerbations may be disappointing. In this situation the higher oral dose of 750 mg twice daily should be used, which is generally considered to produce equivalent blood levels to 200 mg twice daily by the intravenous route. Ciprofloxacin is commonly used as an effective parenteral agent, usually in combination with an aminoglycoside, for treating infective exacerbations in patients with cystic fibrosis and in whom *Ps. aeruginosa* is known to be a major colonist; however, there are less costly alternatives and the prescriber should be guided by the sensitivities and clinical response.

### Other fluoroquinolones

Ofloxacin has a broadly similar antimicrobial spectrum to ciprofloxacin. Although its *in vitro* activity against *Ps. aeruginosa* is lower than that of ciprofloxacin, it is probably as effective in clinical practice for the indications described in the preceding section [267–269]. This may be a consequence of its superior kinetics as it has an oral bioavailability of about 90% compared with approximately 70% for ciprofloxacin. It is administered orally at a dose of 400 mg once or twice daily according to the severity of the infection. The intravenous dose is 200–400 mg twice daily. The adverse effects profile is similar to ciprofloxacin but there is no potentiation of theophylline with this drug [257].

Lomefloxacin (not available in the UK) is ineffective against the pneumococcus and less effective against *Pseudomonas* spp. but has been used as a second-line antibiotic in infective exacerbations of chronic bronchitis. Sparfloxacin (not available in the UK) has improved activity against aerobic Gram-positive cocci including the pneumococcus while retaining Gram-negative activity, with antipseudomonal activity intermediate between that of ciprofloxacin and ofloxacin [270]. As with ofloxacin, it does not appear to interfere with the metabolism of theophylline. It has a long plasma half-life, permitting once-daily dosing. It has been used for the oral treatment of lower respiratory tract infection, with a loading dose of 400 mg followed by a once-daily dose of 200 mg. Although only a small proportion of this drug is excreted in the urine, dose adjustment is required in severe renal failure (creatinine clearance <30 mL/min). Drug regulatory authorities in some countries where lomefloxacin and sparfloxacin have become available have found it necessary to issue guidance notes or restrictions on their usage because of an increased frequency of photosensitivity reactions with these two class members.

Grepafloxacin is one of a number of newer fluoroquinolones (including clinafloxacin and trovafloxacin) currently undergoing clinical assessment [271]. It is rapidly absorbed and is the most hydrophobic of the

fluoroquinolones, with good tissue penetration. It is mainly metabolized, only a small proportion being excreted unchanged in the urine. Its elimination half-life is about 12 h, allowing once-daily administration; 300–600 mg daily has been used in clinical trials. It has improved *in vitro* activity against *Strep. pneumoniae*, while retaining good activity against *H. influenzae* and *Moraxella catarrhalis* but with reduced antipseudomonal efficacy. It has recently been *withdrawn* from use because of rare reports of *torsades de pointes*.

Levofloxacin (available in the UK as oral and parenteral formulations) is an optical isomer of ofloxacin with excellent oral bioavailability and better Gram-positive cover than ciprofloxacin (including *in vitro* activity against MRSA) at the expense of significantly inferior Gram-negative cover.

Clinafloxacin (not available in the UK) is well absorbed and 50% is excreted unchanged in the urine. It has powerful *in vitro* activity against a wide range of respiratory pathogens. It is more effective than ciprofloxacin against *Strep. pneumoniae* and also seemingly has useful activity against methicillin-sensitive *Staph. aureus* and MRSA. It has a high degree of activity against Gram-negative organisms, including *Ps. aeruginosa*, and unlike ciprofloxacin is effective against most anaerobes.

The critical physician will be only too aware of pharmaceutical false dawns, and clinical roles for the newer orally administered quinolones have yet to be established and defined. They are unlikely to constitute optimal therapy in severe cases of pneumococcal pneumonia.

### Chloramphenicol

Chloramphenicol was the first broad-spectrum antibiotic to be discovered. It is now produced synthetically having been originally obtained from a soil *Streptomyces*. It is a predominantly bacteriostatic but nevertheless potent antimicrobial, being particularly effective against *H. influenzae* and *Salmonella typhi*. However, its original wide-ranging use has been severely curtailed in developed countries because of its potential to cause bone marrow toxicity.

The mode of action of chloramphenicol involves the inhibition of bacterial protein synthesis. Although active against a wide range of respiratory pathogens, including most Gram-positive and Gram-negative aerobic and anaerobic bacteria, antibiotics that are equally effective in the clinical setting but less potentially toxic are now available for use against most of these. Bacterial resistance to chloramphenicol may occur and can include organisms such as *H. influenzae* and *S. typhi*, although this is rare in Western practice. The unrestricted sale of chloramphenicol in developing countries has probably been a factor in promoting resistance in these organisms [272].

Chloramphenicol is available in oral form, including a

more palatable but less rapidly absorbed ester for children, and as a solution for intravenous administration. The drug diffuses well and achieves therapeutic concentrations in the brain. It is metabolized by the liver and the bulk of renal excretion is as inactive metabolites so that dose reduction in renal insufficiency is unlikely to be needed, although it may be necessary in hepatic disease [273]. It is possible to assay chloramphenicol in the blood, in which case the level of the drug should be maintained between 10 and 25 µg/mL. The usual oral dose is 500 mg 6-hourly, while the intravenous dose is 50 mg/kg daily in divided doses every 6 h.

Adverse effects include a common dose-related reversible form of marrow suppression, in which anaemia, leucopenia and thrombocytopenia may occur due to inhibition of protein synthesis [274,275]. A much rarer and usually fatal form of marrow suppression may occur. This is not dose-related, occurring idiosyncratically, sometimes even with topical application, and usually producing aplastic anaemia [249]. Epidemiological evidence from the USA suggests that this complication occurs once every 24 500–40 800 systemic prescriptions [276]. This is approximately 13 times the expected occurrence of aplastic anaemia in the general population as a whole. It is usual for this complication to occur not during but some weeks or even months after completion of the course of treatment.

Systemic chloramphenicol should not be prescribed for trivial infections and is now seldom used for respiratory disease in developed countries. It has been used as an alternative to tetracycline for treating spotted fevers due to rickettsial infection in pregnancy and in young children. It is much more widely used in countries where the choice of antibiotics is limited as a result of cost. In such circumstances, it may be used for serious infections caused by *H. influenzae*, *Salmonella*, *Ps. pseudomallei* and in both pneumococcal and meningococcal infection when the patient is allergic to penicillin. The physician who uses chloramphenicol must be able to justify the choice on good grounds in view of the small but real possibility of severe marrow aplasia.

## Antimicrobial agents for use in fungal infections

The applications of these drugs in respiratory disease are discussed in Chapter 21. As the prevalence of immunosuppression in patients has increased so has the incidence of opportunistic fungal infection, particularly in those undergoing intensive cytotoxic chemotherapy, bone marrow and solid organ transplantation and in the AIDS population. The use of systemic antifungal antibiotics has increased in parallel. Antifungal agents are also used in the treatment of endemic mycoses, including blastomycosis, coccidioidomycosis and histoplasmosis. These agents

include amphotericin (intravenous); the azole antifungals ketoconazole (an oral imidazole, miconazole being an older and more toxic parenteral member of this group), fluconazole (an oral or intravenous triazole) and itraconazole (a newer oral triazole); and the older fluorinated pyrimidine analogue flucytosine (intravenous in the UK, oral in the USA). Reliable therapeutic data comparing the use of amphotericin with the newer azoles in serious infections are unfortunately sparse but it has become clear that some of the chronic indolent endemic mycoses, such as histoplasmosis, blastomycosis and coccidioidomycosis, may respond well to ketoconazole or itraconazole; that itraconazole is effective for treating aspergillosis and sporotrichosis; and that fluconazole is an effective treatment for candidaemia and for meningeal involvement in cryptococcosis and coccidioidomycosis.

The reader will realize that although *Pneumocystis carinii* may be regarded as a fungus in terms of taxonomy, in terms of therapeutics it is not, so that in practice the main causes of fungal pneumonia in compromised hosts are *Aspergillus* spp. and *Cryptococcus neoformans*.

### Amphotericin

Amphotericin (amphotericin B, Fig. 9.7) remains the drug of choice for most serious systemic mycotic infections. Like nystatin it is a polyene antifungal antibiotic, being the only member of this group that can be given parenterally. It is produced by the soil streptomycete *Streptomyces nodosus* and apparently has its effects by binding to sterols in the fungal cell membrane, increasing the permeability of this biological barrier and causing the normal cell contents to leak out.

#### Spectrum of activity against respiratory pathogens

Amphotericin is active against most fungi, including opportunists such as *Aspergillus* spp., *Cryptococcus neoformans*, *Candida* spp., *Sporothrix schenckii* and the causes of endemic mycoses, found mainly but not exclusively in North American central river valleys and Latin America, such as *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomycetes dermatitidis* and *Paracoccidioides brasiliensis*.

Fig. 9.7 Structure of amphotericin B.

#### *Administration, distribution and excretion*

Amphotericin is insoluble in water, having detergent-like properties with hydrophobic and hydrophilic regions; thus the standard formulation is presented as a deoxycholate complex that provides a colloidal suspension for intravenous administration. The drug is widely distributed and highly protein-bound, particularly to lipoproteins, and is poorly dialysable. It is seemingly concentrated extravascularly in poorly defined sites that may include the liver, spleen, kidneys and lungs, undergoing degradation *in situ*, with less than 10% being excreted in biologically active form in the urine. Blood levels are not significantly affected by hepatic or renal failure. The plasma half-life of the drug is over 24 h but plasma levels do not necessarily relate to therapeutic efficacy and the total elimination half-life is over 2 weeks so that small quantities of the drug may be detected in the urine for over a month after completion of a course of treatment [277].

A number of lipid formulations of amphotericin have been produced in an attempt to decrease renal toxicity without reducing efficacy. These formulations seemingly transfer the amphotericin from the liposome or lipid complex to the fungal cell wall more efficiently with less attachment to host cell membranes. The compounds include an encapsulated phospholipid vesicle or liposome compound (AmBisome), a sodium cholesteryl complex (Amphocil) and a further amphotericin–lipid complex (Abelcet). All these formulations are less nephrotoxic but probably have no advantage in terms of efficacy and are extremely costly. They may be used in circumstances when renal toxicity precludes conventional amphotericin therapy.

#### *Dosage*

After a test dose (see below), an initial dose of 0.25 mg/kg daily infused in 5% dextrose (10 mg/dL), *not* saline, over 2–4 h is recommended, increasing by 10–15 mg daily to the usual dose range of 0.5–1.0 mg/kg according to individual patient tolerance and response. Higher doses of 1.0–1.5 mg/kg daily may be used in severely ill, often neutropenic patients with invasive aspergillosis until improvement is seen. Prolonged courses of treatment are sometimes necessary in order to prevent relapse, according to clinical circumstances. In such cases, and as the drug has a long half-life, a dosage schedule of say 0.5 mg/kg daily is sometimes switched to 1.0 mg/kg on alternate days for convenience [278].

#### *Adverse effects*

Nausea, anorexia, vomiting, headache and febrile reactions may occur in most patients, particularly at the onset of treatment, but respond to symptomatic measures and

may be reduced by using a 4-hourly infusion rate. Anaphylactic reactions are rare but it is nevertheless recommended that a test dose is given before the first full infusion of any new course, 1 mg in 10 mL 5% dextrose being infused over 20 min and the patient observed for a further 30 min [278]. The most important dose-limiting adverse effects are renal, amphotericin both reducing glomerular filtration rate and causing renal arteriolar vasoconstriction that may lead to renal failure, particularly if used in combination with other potentially nephrotoxic drugs or in the presence of volume depletion or hypotension. Some degree of azotaemia is to be expected (80% of patients); however, if the serum creatine exceeds three times the upper limit of normal in severe or life-threatening fungal disease it is advisable to discontinue amphotericin for 1 day, thereafter resuming at half the previous dosage, followed by a gradual increase to the previous dose over 2–3 days if renal function permits [278]. Adequate hydration should be ensured until renal function improves. Electrolytic abnormalities such as hypokalaemia and hypomagnesaemia may occur. Mild normochromic normocytic anaemia may also occur, usually as a result of marrow suppression. Thrombophlebitis at a peripheral infusion site may cause problems and may be minimized by avoiding slower infusion rates and concentrations of greater than 0.1 g/L or by using a central line. Neurotoxic side-effects include peripheral neuropathy as well as rare central effects such as fitting. Cardiotoxicity with dysrhythmias is also described [277].

#### *Principal uses in respiratory medicine*

Because of its toxicity, parenteral amphotericin is only used when progressive, potentially fatal fungal infection (other than *Pneumocystis carinii*) has been confirmed or is strongly suspected. It has been described in North American practice as ‘the drug that we all love to hate but use when the going gets tough’ and it remains the antifungal agent of choice in the extremely ill patient. Such ‘tough’ situations usually arise in patients who are immunocompromised as a result of either cytotoxic or immunosuppressive therapy, particularly those undergoing chemotherapy for neoplastic disease, those who have had organ transplants and those with HIV infection. Major risk factors are therefore neutropenia, systemic corticosteroid use and AIDS, fungal pneumonia being suspected in any immunocompromised host with lung infiltrates who is not responding to conventional antibiotics. Such fungal infections include those caused by *Aspergillus* spp., *Cryptococcus neoformans* and *Candida* spp.

Amphotericin remains the drug of choice in the following situations:

1 immunocompromised and/or neutropenic patients with invasive aspergillosis;

2 immunocompromised and/or neutropenic patients with blastomycosis, also being used in the immunocompetent patient with life-threatening illness;

3 in life-threatening progressive disseminated histoplasmosis (at least for induction), usually in immunocompromised patients especially those with AIDS;

4 for induction in severe paracoccidioidomycosis, usually in immunocompromised patients especially those with AIDS;

5 for initial treatment of life-threatening cases of sporotrichosis [279].

It is used in severe chronic pulmonary coccidioidomycosis, although itraconazole or ketoconazole may be preferred [279,280]. It may be used with flucytosine support in severe pulmonary cryptococcosis and this combination is also the treatment of choice in cryptococcal meningitis [280]. When cryptococcal meningitis occurs in AIDS, fluconazole is an effective primary therapy and is used anyway as 'long-term' maintenance once remission has been achieved [279]. Amphotericin is the treatment of choice for serious disseminated candidal infection, any vascular cannulae that may have been colonized also being removed. Flucytosine is sometimes added initially for synergism, depending on the severity of the situation [280]. Fluconazole is a less toxic alternative that may be used in patients without neutropenia [281]. When fungi are recovered from bronchoscopic lavage fluid it should not be inferred that they are necessarily the cause of pneumonia and the finding of *Candida* spp. in lavage fluid is of little value as they are common colonists. *Candida* pneumonia does not occur in isolation but rather as part of a disseminated invasive candidiasis associated with candidaemia. Critically ill patients who have been treated with broad-spectrum antibiotics and whose immunity may have been impaired by a number of factors including corticosteroid use are at risk of disseminated candidal infection [282]. The decision to treat fungal pneumonia is based on clinical features, e.g. cavitating infiltrates and haemoptysis (see Chapter 21), unless tissue invasion has been demonstrated in lung tissue obtained transbronchially or by other means.

### Itraconazole

Itraconazole (Fig. 9.8), like fluconazole, is a triazole with a better safety profile than the earlier imidazoles such as ketoconazole. As with all azoles, it has its effect by blocking an enzyme concerned with the synthesis of ergosterol, the main fungal cell wall sterol, which damages this membrane with resultant impaired cell growth and replication [280].

#### Spectrum of activity against respiratory pathogens

Itraconazole is active *in vitro* against most fungal

Fig. 9.8 Structure of itraconazole.

pathogens. It is the only azole with good activity against *Aspergillus* spp., comparing favourably in this regard with amphotericin. Other susceptible fungi include *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis*, *Paracoccidioides brasiliensis*, *Sporothrix schenckii*, *Cryptococcus neoformans* and *Candida* spp. although *Candida* other than *C. albicans* and other yeasts may be less susceptible.

#### Administration, distribution and excretion

Itraconazole, like ketoconazole and amphotericin but unlike fluconazole, is highly insoluble in water and is available only in oral form. Absorption is very significantly improved if it is taken immediately after food, and is also improved by the presence of acid and therefore diminished by  $H_2$  antagonists and the like. As with ketoconazole but unlike fluconazole, itraconazole is highly bound to plasma proteins (99%), particularly to lipoproteins, and is poorly dialysable. Plasma concentrations of itraconazole are therefore low but tissue concentrations are higher. Like ketoconazole but unlike fluconazole, cerebrospinal fluid (CSF) concentrations are negligible, even in the presence of meningitis. Itraconazole is metabolized in the liver, the metabolites being excreted in the faeces and negligible amounts are found in the urine. No dosage adjustment is therefore needed in renal insufficiency but the drug may accumulate in the presence of significant hepatic dysfunction. The half-life of itraconazole is about 24 h, so that once-daily dosing is possible in appropriate circumstances [279,283].

#### Dosage

The total daily dose and duration of treatment vary according to severity and nature of the infection and the response to the drug. Invasive or disseminated fungal infections may be treated with 200 mg twice daily, although in patients with serious infections many prefer to use 200 mg three times daily for the first 3 days in order to achieve serum concentrations high enough to exert a pharmacological effect more quickly. Thereafter doses of 100–400 mg daily may be used. A long-term maintenance dose of 200 mg daily is usual in AIDS and the same dose

may be used prophylactically in neutropenic patients. Doses greater than 200 mg are conventionally divided.

#### *Adverse effects and interactions*

One of the principal advantages of itraconazole over ketoconazole is its lower rate of toxicity [284]. The commonest adverse effect is nausea and vomiting (<10% of patients) but this does not often necessitate discontinuance of the drug. Tolerance may be improved in such cases by division of the dose. A mineralocorticoid effect with hypokalaemia and oedema may occur at higher doses. Abnormalities of liver function (aminotransferase elevation) have been observed in less than 5% of patients receiving long-term itraconazole but these appear to be reversible on discontinuance and serious hepatotoxicity is rare [284]. Allergic rashes and pruritis sometimes occur.

The effect of drugs that reduce gastric acid has already been mentioned in the context of absorption. Drugs that induce hepatic cytochrome P450-dependent enzymes may increase the metabolism of itraconazole and therefore reduce its bioavailability, with increased levels of the interacting drug. These include rifampicin, phenytoin, carbamazepine and phenobarbital (phenobarbitone). Drugs that are themselves metabolized by the cytochrome P450 enzyme system are potentiated by azoles including itraconazole. These include the antihistamines terfenadine and astemizole and the gut motility stimulant cisapride, with the potential for serious cardiac dysrhythmias including torsades de pointes. Cyclosporin levels may be increased with subsequent renal damage so that the dose of cyclosporin should be reduced by half and levels monitored more closely if the two have to be used together [285]. The effect of warfarin, simvastatin and digoxin may be potentiated.

#### *Principal uses in respiratory medicine*

Itraconazole may be used as an effective alternative to the more toxic amphotericin in the treatment and control of chronic necrotizing aspergillosis [286]. Itraconazole has also been used successfully to treat invasive aspergillosis [287], although amphotericin is generally used in the iller patient. Itraconazole has been proposed as an adjunctive therapy for patients with allergic bronchopulmonary aspergillosis who are corticosteroid dependent [288].

Encouraging results have been obtained with itraconazole at doses of 200 mg daily for approximately 6 months in the treatment of less severe cases of blastomycosis without meningeal involvement [280,289]. Once again, amphotericin remains the treatment of choice in patients whose infection is life-threatening, although once control has been achieved, continued treatment with oral itraconazole may be appropriate [290].

Acute pulmonary coccidioidomycosis occurring end-

emically in an immunocompetent host is usually self-limiting and requires no treatment. Those who develop the more chronic form of pulmonary disease that resembles tuberculosis and those who are immunosuppressed need treatment and itraconazole has been used successfully in this context [291]. Good comparative data comparing itraconazole with ketoconazole and amphotericin in the treatment of coccidioidomycosis are lacking but itraconazole is currently the drug of choice [280]. Itraconazole is not regarded as a first-line drug in patients with meningeal infection because of its poor CSF penetration, although it has been used for this purpose [292].

Some small series have also claimed to show that itraconazole can be effective in cryptococcal meningitis [293], fluconazole or amphotericin ordinarily being used in this situation [280]. In patients unable to take fluconazole, it has been used as consolidation therapy once cryptococcal meningitis in AIDS patients has been controlled [294].

Acute primary pulmonary histoplasmosis in an immunocompetent patient usually takes the form of a mild self-limiting illness so that no specific antifungal treatment is required [295]. Itraconazole is often the drug of choice in cases when symptoms are more severe or the disease becomes chronic, mimicking tuberculosis, or in disseminated disease in immunodeficient patients such as those with AIDS, although amphotericin remains preferable for initial treatment in more severe life-threatening disease [279,280,289]. Itraconazole is also the drug of choice in AIDS for maintenance therapy once a remission has been obtained [296,297]. Paracoccidioidomycosis may produce serious pulmonary infection in immunodeficient patients such as those with AIDS; in severe disease treatment with amphotericin is required, whereas in less severe illness itraconazole may be used and may also be effective in maintaining a remission [282]. Itraconazole may be more effective than fluconazole for treating pulmonary sporotrichosis [298], amphotericin as usual being reserved for severe infections. Itraconazole with flucytosine has been used for the treatment of oesophageal candidiasis when the organism has developed fluconazole resistance [299].

#### *Fluconazole*

Fluconazole (Fig. 9.9), like itraconazole, is a triazole with the same cell membrane destabilizing action common to all azoles. It also has a better safety profile than the earlier imidazoles such as ketoconazole.

#### *Spectrum of activity against respiratory pathogens*

Fluconazole has good activity against *Candida albicans*, although a few candidal species may be resistant and resistance may emerge when it is used as long-term prophylaxis [280]. It is also effective against *Cryptococcus*

Fig. 9.9 Structure of fluconazole.

*neoformans* and *Coccidioides immitis* but is inactive against *Aspergillus* spp. and cannot be relied upon for infections caused by *Histoplasma capsulatum* and *Blastomyces dermatitidis* [280,290,300,301].

#### Administration, distribution and excretion

Fluconazole, unlike itraconazole, ketoconazole and amphotericin, is a small molecule, with lower lipophilicity and high solubility in water. It is available in both oral and intravenous formulations. In contrast to ketoconazole and itraconazole, absorption does not require the presence of acid and is therefore unaffected by  $H_2$  antagonists, antacids, etc. Fluconazole, unlike itraconazole and ketoconazole, is minimally bound to plasma proteins and is dialysable. It is widely distributed and high CSF concentrations are achieved. The elimination half-life of fluconazole is usually well over 24 h, so that once-daily dosing is possible [279,283]. Unlike itraconazole, fluconazole is largely (80%) excreted unchanged in the urine, so that dosage adjustment is recommended by the manufacturer if the creatinine clearance is 40 mL/min or less.

#### Dosage

The total daily dose and duration of treatment vary according to the type and severity of infection and response. Once-daily dosing is used, except in renal failure in which case the dosing interval may be lengthened. Invasive or disseminated fungal infections may be treated with oral or intravenous fluconazole 400 mg on the first day and 200–400 mg daily thereafter until completion of the course, which in the case of cryptococcal infections may be at least 6 weeks. Prevention of relapse of cryptococcal infection in AIDS may be achieved by lifelong maintenance doses of 100–200 mg daily. According to an assessment of risk, doses of 50–400 mg daily may be used prophylactically in neutropenic patients who have received cytotoxic chemotherapy/radiotherapy for cancer (although survival benefit in this context is questionable). Oropharyngeal and oesophageal candidiasis may be treated with 50–100 mg daily for 7–14 days, or longer in

severely immunocompromised patients [300].

#### Adverse effects and interactions

Fluconazole is well tolerated. The commonest adverse effects are nausea and other gastrointestinal symptoms but these occur in less than 5% of patients [300]. Rashes, including Stevens–Johnson syndrome, may occur but are uncommon. Mild abnormalities of liver function (amino-transferase elevation) have been reported in less than 7% of patients but severe hepatotoxicity is extremely rare.

Of the drugs that induce the hepatic cytochrome P450-dependent enzyme system, rifampicin increases the metabolism of fluconazole and therefore reduces its bioavailability. Drugs that are themselves metabolized by the cytochrome P450-dependent enzyme system may be potentiated by azoles including fluconazole. Because of this, the antihistamines terfenadine and astemizole and the gut motility stimulant cisapride are also best avoided with fluconazole in view of the possibility of serious cardiac dysrhythmias, including torsades de pointes. Cyclosporin levels may be increased in transplant patients and should be monitored particularly if higher doses of fluconazole have to be used. The effects of warfarin, theophylline, rifabutin (risk of uveitis), phenytoin, zidovudine and oral sulphonylurea hypoglycaemic agents may be potentiated [279,300].

#### Principal uses in respiratory medicine

Pulmonary cryptococcosis in immunosuppressed patients is usually treated with amphotericin, with or without flucytosine, although fluconazole has been used as a less toxic alternative, being effective in meningitis [279,302,303]. In AIDS patients, lifelong maintenance fluconazole is necessary once the primary cryptococcal infection has come under control [304]. Amphotericin is also often used for the first 2 weeks for induction therapy when cryptococcal infection involves the meninges, as it commonly does in AIDS, after which treatment is usually maintained with fluconazole, which is the drug of choice in this situation [294].

There are few data on the relative efficacy of the azoles and amphotericin in the treatment of pulmonary coccidioidomycosis but fluconazole is appropriate if the meninges are involved [305].

Fluconazole may be used as a less toxic alternative to amphotericin for treatment in the intensive care unit of the severely ill non-neutropenic patient with disseminated candidiasis but without any major immunodeficiency, in which situation *Candida albicans* is the usual pathogen [306,307]. Amphotericin remains the preferred agent in the management of other patient groups with candidaemia and haematogenously disseminated candidiasis [306]. Fluconazole is a highly effective agent when used to treat

oropharyngeal or oesophageal candidiasis in patients with AIDS and in cancer patients with neutropenia [300]. There appears to be no clear survival benefit when antifungal agents such as fluconazole are used as so-called 'primary prophylaxis' in cancer patients with neutropenia [308] or in patients with advanced HIV infection ( $CD4^+$  lymphocytes  $\leq 0.05 \times 10^9/L$ ), although in the latter group reduced morbidity from candidiasis and cryptococcosis was shown [309]. The use of prophylactic fluconazole may encourage the emergence of resistant potentially pathogenic yeasts such as *Candida krusei* [310].

Fluconazole is not an effective treatment for aspergillosis [280].

### Ketoconazole

Ketoconazole (Fig. 9.10) was the first oral azole that was useful for treating systemic infections. It is an imidazole with a shorter half-life and narrower spectrum than the newer more expensive triazoles such as itraconazole and fluconazole. It also has more adverse effects than the newer drugs fluconazole and itraconazole but is less expensive, which may be important for patients receiving long-term treatment. As with the other azoles, it has its effect by blocking an enzyme concerned with ergosterol synthesis so that the integrity of the fungal cell membrane is impaired.

#### Spectrum of activity against respiratory pathogens

Ketoconazole has activity against *Candida*, although species other than *C. albicans* and other yeasts may be resistant. It also has activity against *Histoplasma capsulatum*, *Blastomyces dermatitidis* and *Paracoccidioides brasiliensis*. It has some activity against *Coccidioides immitis* but is inactive against *Aspergillus* spp. and *Cryptococcus neoformans*.

#### Administration, distribution and excretion

Ketoconazole, like itraconazole and amphotericin but unlike fluconazole, is highly insoluble in water. It is avail-

able only in oral form. As with itraconazole, absorption requires the presence of acid and is therefore diminished by  $H_2$  antagonists, proton pump inhibitors, etc. As with itraconazole but unlike fluconazole, ketoconazole is highly bound to plasma proteins (99%) and is not dialysable. Penetration to most tissues is good but CSF concentrations, as with itraconazole but unlike fluconazole, are negligible even in the presence of meningitis [311]. Ketoconazole is metabolized in the liver, the metabolites being excreted in the faeces, so that negligible amounts are found in the urine. No dosage adjustment is therefore needed in renal insufficiency but the drug may accumulate in the presence of significant hepatic dysfunction and, since it may itself cause idiosyncratic hepatotoxicity, is best avoided in this situation.

#### Dosage

When used for serious systemic mycoses, the usual dose is 400 mg once daily with food to reduce nausea.

#### Adverse effects and interactions

Adverse effects with ketoconazole include anorexia, nausea, vomiting and other gastrointestinal symptoms, which occur in about 17% of patients taking 400 mg (two tablets) daily [312]. Rashes may also occur. Asymptomatic mild elevation of the transaminases is not uncommon and is usually transient. The most serious potential adverse effect is symptomatic hepatitis, which is rare but occurs idiosyncratically at any time during treatment and which may progress rapidly, being accompanied by profound derangement of liver function tests with jaundice and occasionally a fatal outcome. It is recommended that liver function tests be checked before treatment, after 14 days and monthly thereafter until completion of the course. Whether this protects patients is unproven, but at least it serves to keep both the physician and the patient alert for the complication. In contrast to the newer triazoles itraconazole and fluconazole, ketoconazole has endocrine effects by inhibiting the cytochrome P450 enzymes needed for adrenal and gonadal steroid hormone production; thus production of both cortisol and testosterone may be suppressed, particularly if the 400 mg daily dose is exceeded. Impotence, infertility, gynaecomastia, dysfunctional uterine bleeding and, rarely, adrenal insufficiency may result [313].

Drug interactions are broadly similar to those described for itraconazole. Isoniazid may also cause increased metabolism of ketoconazole and cyclosporin levels are more likely to be raised by ketoconazole than by itraconazole and fluconazole [280]. This observation has led some to combine ketoconazole with cyclosporin deliberately after transplantation in order to reduce the requirement and therefore the cost of cyclosporin [314].

Fig. 9.10 Structure of ketoconazole.

*Principal uses in respiratory medicine*

Ketoconazole may be used for the treatment of chronic pulmonary histoplasmosis or blastomycosis in immunocompetent hosts, provided there is no meningeal involvement, and is cheaper though less well tolerated than itraconazole. Improvement may take a month to become evident and treatment is continued for 6 months to 1 year [280,290,312]. It is not effective in histoplasmosis when this occurs in association with AIDS [297]. Ketoconazole is also effective in paracoccidioidomycosis [315]. It may control disseminated coccidioidomycosis temporarily but relapse usually occurs on discontinuance of the drug [301].

Ketoconazole is ineffective for the treatment of both aspergillosis and cryptococcosis and for any disseminated mycosis involving the meninges. Rapidly progressive deep mycoses are more reliably treated with amphotericin. Systemic ketoconazole should not be used for superficial fungal infections in view of its potential for causing adverse effects, particularly hepatitis.

*Flucytosine*

Flucytosine is a synthetic fluorinated pyrimidine analogue that has a relatively narrow spectrum of antifungal activity. The drug is metabolized to its active form, 5-fluorouracil, which interferes with fungal protein synthesis. Flucytosine is active against many yeasts and yeast-like organisms. Although well absorbed by mouth and with excellent distribution, which includes the CSF, the only formulation available in the UK is for intravenous infusion. The usual daily dose is 150–200 mg/kg i.v. divided as four doses over 24 h. It is not usually used alone because of the emergence of resistance (which is more likely than with fluconazole) but may be used in combination with amphotericin for deep-seated infection by susceptible organisms, this being standard therapy in the treatment of seriously ill patients with cryptococcal meningitis; fluconazole is used for milder cases and for maintenance therapy in AIDS. Flucytosine may also be combined with amphotericin to treat systemic candidiasis, particularly when the CNS is involved. It has weak activity against *Aspergillus* spp. and *Histoplasma capsulatum*. *Blastomyces dermatitidis* and *Coccidioides immitis* are resistant. It is largely excreted unchanged by the kidneys, so that the dose must be adjusted in renal impairment according to creatinine clearance. Bone marrow suppression may occur, with leucopenia and thrombocytopenia, and this may be more problematical in patients with AIDS in whom the bone marrow may already be suppressed as a result of other factors. Nausea, vomiting and diarrhoea may also occur [316].

**Antimicrobial agents for use in viral infections**

Antiviral chemotherapy poses considerable problems compared with antibacterial treatment, in which the metabolism of the invading organism is sufficiently different from that of the host cells to enable the development of agents toxic to the bacterium but not to the patient. As virus particles manipulate the host's cellular structures for their own ends, such a clear separation of the target organism from the host becomes more difficult; nevertheless, recent developments in molecular biology have permitted the synthesis of various compounds, the majority of which are intended to interfere with the viral replicative process in infected host cells without interfering with nucleic acid synthesis in normal cells. A number of these substances either show promise or are of established, although limited, clinical value.

Viruses that may be targeted in adult respiratory medicine include members of the Herpesviridae family, HIV and the influenza A virus. The Herpesviridae contains herpes simplex virus (HSV) types 1 and 2, varicella-zoster virus (VZV) and cytomegalovirus (CMV), all of which may cause severe illness in immunocompromised patients. VZV may also cause severe pneumonia in immunocompetent adults (see Chapter 13). Increased understanding of the structure and pathogenicity of HIV, responsible for AIDS [317], has given impetus to further developments in the field of antiviral chemotherapy. As with antibacterial agents, resistance may emerge with antiviral agents as a result of the occurrence, during replication, of mutations in the genes that code for the drug target or activator [318]. A description of some antiviral agents currently relevant to respiratory medicine follows.

**Aciclovir in VZV and HSV infections**

Aciclovir (acyclovir) is an antiviral purine nucleoside analogue that is the agent of choice in the treatment of infection by both HSV types 1 and 2 and VZV.

*Mode of action*

Aciclovir (Fig. 9.11) is activated *in vivo* by virally produced thymidine kinase, which phosphorylates it to form aciclovir monophosphate in infected cells [319]. Further intracellular phosphorylation takes place to form aciclovir triphosphate, which reaches sufficient concentration in infected cells to inhibit viral DNA polymerases, which in turn prevents the production of new viral DNA chains [320,321]. As the action of this drug is to prevent replication of viral DNA, it is unlikely to eradicate latent infection.

Fig. 9.11 Structure of aciclovir.

#### *Spectrum of activity*

Aciclovir is active against HSV infections, controlling rather than eradicating the virus. It is active against VZV but has little activity against Epstein–Barr virus (EBV) and CMV is resistant [322,323]. Neither EBV nor CMV produce thymidine kinase and this probably accounts for their relative immunity. Aciclovir-resistant strains of HSV have been demonstrated in immunocompromised patients and these too lack thymidine kinase [324]. These HSV mutants remain sensitive to drugs such as foscarnet that do not require thymidine kinase for activation [325]. Clinical studies of aciclovir have shown it to be effective in both HSV and VZV infections and to be more effective than another antiviral nucleoside, vidarabine, which is no longer available for systemic use [326,327].

#### *Administration, distribution, excretion and dose*

Aciclovir may be taken orally but only 20% of the dose is absorbed. This may produce adequate blood levels for mucocutaneous HSV infections and for chickenpox in immunocompetent adults but for any serious infection the intravenous route is preferred. The drug is widely distributed and reaches the CSF, permitting one of its principal extrathoracic uses, the treatment of HSV encephalitis. The plasma half-life is 2–3 h and most of the drug is excreted unchanged in the urine, so that the dose should be reduced in renal insufficiency [328], an estimated creatinine clearance of less than 50 mL/min being an indication for dosage reduction according to the manufacturer's recommendations [325,329].

The oral dose for treating mucocutaneous HSV in immunocompromised patients is 200–400 mg five times daily for 5–10 days [325]. The oral dose for HSV prophylaxis in immunocompromised patients, such as those undergoing induction chemotherapy or transplantation, is 200–400 mg four times daily. The oral dose for VZV infections is 800 mg five times daily for 7 days.

The usual intravenous dose for HSV infections in

immunocompromised patients is 5 mg/kg infused over 1 h and repeated 8-hourly. The dose may be increased to 10 mg/kg i.v. 8-hourly in severe VZV infection. This higher dose is also used in HSV encephalitis [325]. The treatment is normally continued for 5 days for uncomplicated HSV infection and up to 10 days for more serious infections, including encephalitis.

Topical preparations exist for skin (cream, not for mucous membranes) and eyes (eye ointment).

#### *Adverse effects*

Aciclovir shows a remarkable lack of toxicity at standard doses. Intravenous infusions may produce local irritation. Bolus intravenous injection may produce crystal formation in the renal tubules. Infusions of more than 5 mg/kg may have a similar effect, with a reversible rise in plasma creatinine [330]. If such high doses are required, then adequate hydration should be ensured. Nausea, vomiting and encephalopathy have been reported with higher doses. Disturbances of liver function tests may occur.

#### *Principal uses in respiratory medicine*

The application of aciclovir to immunocompetent adult patients with respiratory disease is largely confined to the hospital treatment of chickenpox pneumonia, as other susceptible viral infections in this group are usually mild and self-limiting [331], although a recent study has shown that adults with uncomplicated chickenpox recover quicker when treated with aciclovir and that this is cost-effective management [332]. A retrospective controlled trial involving 38 patients was conducted to determine if aciclovir was effective in the early treatment of varicella pneumonia in otherwise healthy adults, better results being obtained in the treatment group [333]. In immunosuppressed patients, such infections are more likely to be life-threatening; however, provided that treatment is started within 72 h of the onset of zoster or chickenpox, there is evidence that cutaneous and visceral spread is limited [325,334]. A placebo-controlled trial of aciclovir in immunosuppressed children with chickenpox has shown the drug to be effective in preventing the development of pneumonia [335]. Once disease is fully established, the results are poor [335]. There is evidence to suggest that aciclovir was clinically more effective than vidarabine in VZV infection, the latter drug being no longer available for systemic use [326,336]. Aciclovir has been shown to be effective both prophylactically and as treatment for mucocutaneous HSV lesions in immunocompromised hosts [325,337–339]. Aciclovir does not alter the clinical course of CMV and EBV infections [325].

Valaciclovir is an ester of aciclovir. Famciclovir is a prodrug of penciclovir, which is pharmacologically related to aciclovir. Both drugs are available for the oral

treatment of mucocutaneous HSV infections and have to be taken less frequently than aciclovir.

## **HIV: principles of antiretroviral therapy**

### **General principles**

HIV infection is mainly caused by HIV-1, HIV-2 being largely confined to West Africa. Both are RNA-containing retroviruses that target CD4+ T lymphocytes. Replication of the virus results in the destruction of these lymphocytes so that the CD4+ count (normal  $0.6\text{--}1.5 \times 10^9/\text{L}$ ) falls progressively, leaving the patient open to those opportunistic infections and neoplasms that characterize AIDS. Rates of opportunistic infection rise significantly when the CD4+ count falls below  $0.2\text{--}0.3 \times 10^9/\text{L}$ . Two viral enzymes that are important in HIV replication have been targeted by antiretroviral drug therapy: (i) viral reverse transcriptase (DNA polymerase) and (ii) viral protease. Reverse transcriptase uses viral RNA as a template to produce DNA that is then incorporated into the host's DNA and transcribed to make more viral RNA. This RNA produces precursor polyproteins that are split by viral protease to produce proteins essential for viral maturation. Those drugs that interfere with DNA transcription by acting on reverse transcriptase of HIV-1 and HIV-2 are the nucleoside analogues, including zidovudine, didanosine (ddI), zalcitabine (ddC), stavudine (d4T) and lamivudine (3TC). The more recent non-nucleoside reverse transcriptase inhibitors such as nevirapine inhibit HIV-1 reverse transcriptase. Those that inhibit HIV protease include ritonavir, indinavir, nelfinavir and saquinavir [340]. Other protease inhibitors and non-nucleoside reverse transcriptase inhibitors (such as nevirapine) have been released or are under investigation [341].

As experience in the management of HIV infection has accumulated, it has become evident that HIV replicates rapidly and has the capacity to become resistant to antiviral agents by spontaneous mutation; when this happens, cross-resistance to drugs of the same class may arise. The use of single drugs is likely to select resistant organisms within days or weeks, hastening treatment failure, so that recent drug strategies making use of more than one agent (along the lines of antituberculous therapy) have emerged in order to forestall this [341,342]. These recommendations have been made largely on the basis of randomized clinical trials and short-term disease activity marker studies [341]. In addition to the CD4+ count, changes in the plasma level of HIV-1 RNA ('viral load') has emerged as an important disease activity marker and thus change in viral load 8–12 weeks after the introduction of treatment may be used as a measure of therapeutic efficacy [341,342]. Although expensive, viral load assays should be con-

ducted, starting with two baseline measurements and then every 3–6 months in untreated HIV-infected patients and more frequently in those receiving antiretroviral therapy [341,342].

Clinical trials are ongoing but three-drug combinations that include two nucleoside analogues and an HIV protease inhibitor (e.g. zidovudine/didanosine/indinavir or zidovudine/lamivudine/indinavir) show promise, the rationale being to suppress viral replication maximally before the immune system is irreparably damaged [343–345]. Although still an area of debate, current opinion has leaned towards this initial three-drug approach and away from recent two-drug recommendations [346]. These recommended the combination of two nucleosides or a nucleoside plus a protease inhibitor, with the option of the addition of a protease inhibitor to the first combination or a nucleoside to the second if the patient fails to respond [342,347]. More recently it has been recommended that the initial treatment of all HIV-infected patients should include an HIV protease inhibitor plus two nucleoside analogues unless contraindicated [340,348]. Debate also surrounds the dilemmas of when treatment should best be started, the initial choice of drugs and when to switch from, or add to, this combination. In the USA, it is considered prudent to start treatment when the CD4+ count falls below  $0.5 \times 10^9/\text{L}$  or if the plasma HIV RNA concentration (viral load) is more than 5000–10000 copies/mL even if the CD4+ count exceeds  $0.5 \times 10^9/\text{L}$ , disease in patients with much heavier viral loads having been found to progress faster than in those with lower viral loads [340,341,346].

Antiretroviral drugs in general are toxic and the manufacturer's summary of product characteristics should be consulted before use.

### **Accidental exposure of staff (needlestick injuries)**

Antiretroviral drugs are also used to treat healthcare workers who have experienced accidental percutaneous exposure to HIV-infected blood, such as might occur with a needlestick injury. The average risk of transmission of HIV infection in this situation is estimated at 0.3% [349]. The data on the effectiveness of postexposure prophylaxis are limited but a retrospective case-control study indicates that risk is related to the size of the inoculum and that zidovudine appears to provide an 81% reduction in the risk of occupational infection [349,350]. In the UK, the Chief Medical Officer's Expert Advisory Group on AIDS has published guidance recommending 24-h access to advice for healthcare workers with prompt (within 24 h, preferably 1–2 h) postexposure prophylaxis using a combination of three antiretroviral drugs for 4 weeks [351,352]. In the USA, guidelines have also been promulgated.

Fig. 9.12 Structure of zidovudine.

### Nucleoside analogues: reverse transcriptase inhibitors

#### Zidovudine

Zidovudine (azidothymidine, AZT, Fig. 9.12) is an analogue of the naturally occurring DNA nucleoside thymidine. It was licensed for use in HIV infection in the UK in 1987 [353]. It is now current practice to use it as a constituent part of combination chemotherapy in the treatment of HIV infection (see above).

#### Mode of action

Zidovudine was found to inhibit the *in vitro* replication of a cytopathic retrovirus, now known as HIV, in human T cells [354,355]. It is active against a broad spectrum of retroviruses including HIV-1 and HIV-2. Zidovudine enters cells and is converted into zidovudine triphosphate. This competes with thymidine triphosphate for a nucleoside-binding site on the growing chains of viral DNA that are being produced by reverse transcriptase, the drug thereby acting as a 'chain terminator' and preventing reverse transcriptase from making DNA copies of viral genomic RNA [354,356].

#### Administration, distribution and excretion

The drug is usually taken orally and is well absorbed, being distributed widely in body fluids including the CSF [354], so that it may be potentially useful in preventing the AIDS dementia complex. It is cleared rapidly from the blood, being metabolized mainly in the liver, and about 25% is excreted unchanged in the urine so that some dose adjustment may be necessary in advanced renal failure. The half-life is very short (about 1 h) but may be prolonged in liver disease because of impaired metabolism. A formulation of the drug is available for intravenous infusion if it cannot be taken orally.

#### Dosage

The dosage schedule from early trial work was 250 mg

orally every 4 h [357], although it soon became apparent that lower doses were as effective but less toxic [358]; thus 500–600 mg daily in two to five divided doses is acceptable, the commonest regimen being 200 mg three times daily. In order to protect the fetus, pregnant women (over 14 weeks' gestation) with HIV infection should be prescribed 100 mg five times daily until the onset of labour, then 2 mg/kg intravenously over 1 h and then 1 mg/kg/h by continuous infusion until the cord is clamped, the infant then continuing oral zidovudine for 6 months. This approach reduces the risk of perinatal transmission from 26% to 8% [359]. The intravenous dose is 1–2 mg/kg every 4 h.

#### Adverse effects

Zidovudine is associated with significant toxicity, the most important manifestations of which are haematological. Anaemia (usually macrocytic) and neutropenia were experienced in almost half the patients receiving the drug in one large early trial [360]. These effects, serious enough to require blood transfusion in some patients and to prevent further treatment with the drug, usually started soon after the onset of treatment and reversed within about 2 weeks of stopping therapy, so that it was possible to recommence at a lower dose. Bone marrow suppression has been found to be dose dependent, also occurring more commonly in patients with advanced disease (CD4+ count  $<0.1 \times 10^9/L$ ), but the blood count should nevertheless be monitored. It is less common nowadays as the drug is used at lower doses than in early studies, so that neutropenia may be found in about 9% of patients with less advanced disease. Neuropathy and myopathy have also been reported but are unusual. Other side-effects include nausea, headache, myalgia and insomnia but usually pass off without stopping treatment. Lactic acidosis may rarely occur, in which case the drug must be stopped.

#### Clinical role

The clinical role of zidovudine is under continuous review, the trend having shifted from monotherapy [357] to two-drug therapy [361,362] and more recently to triple-drug therapy [340,344,345,348], zidovudine being one of a number of possible constituents in these regimens (see above). In the early days of its use as monotherapy, the results of a multicentre, prospective, double-blind, placebo-controlled study involving over 280 patients was published [357]. Those patients entered either had AIDS, with a first episode of *Pneumocystis carinii* pneumonia within the last 4 months, or satisfied inclusion criteria for the AIDS-related complex, which included positive serology for AIDS with either (i) 10% weight loss in the preceding 3 months or (ii) oral candidiasis and one of

the following: unexplained fever, extrainguinal lymphadenopathy, oral hairy leucoplakia, unexplained night sweats, herpes zoster or unexplained diarrhoea. These selection criteria would have tended to exclude patients who were more debilitated as a result of having had clinical AIDS for a longer period. The results of this study showed a highly significant reduction in mortality in the treated group over a period of 24 weeks, probably as a result of a significant reduction in opportunistic infection, which became evident after the sixth week of treatment [357]. There was also improved quality of life in terms of Karnofsky scoring [357,363].

### *Didanosine*

Didanosine (ddI, DDI) is an orally administered purine nucleoside analogue with antiretroviral activity but with relatively little toxicity for bone marrow. It has a half-life of about 12 h and may therefore be given twice daily. It is unstable in acid and has to be taken 1 h before or 2 h after a meal. All formulations contain buffering agents to reduce gastric pH. It reaches the CSF, although less well than zidovudine. About 50% of the drug is excreted unchanged in urine so that dose adjustment is necessary in renal failure. Like zidovudine, it inhibits the replication of HIV by blocking the reverse transcriptase-mediated synthesis of viral DNA. The tablet dose is 125 mg twice daily for patients weighing less than 60 kg and 200 mg twice daily for those weighing more than 60 kg. The main dose-limiting adverse effects are painful peripheral neuropathy and pancreatitis. These are unusual with currently recommended dose levels but the drug should not be used in patients with a previous history of either condition. Nausea, vomiting, diarrhoea and, rarely, liver failure may occur. It was initially used singly, subsequently in double-drug combinations and more recently has been under investigation as triple therapy in combination with zidovudine and a protease inhibitor such as indinavir [364].

### *Zalcitabine*

Zalcitabine (ddC, DDC) is an orally administered nucleoside analogue with antiretroviral activity that also inhibits the replication of HIV by blocking the reverse transcriptase-mediated synthesis of viral DNA. It is usually well absorbed and distributed but reaches the CSF less well than zidovudine; 75% is excreted unchanged in the urine so that dose reduction is necessary if the creatinine clearance is less than 40 mL/min. The usual dose is 0.75 mg 8-hourly. The main dose-limiting side-effect is painful sensorimotor peripheral neuropathy, which occurs in about 20% of patients and necessitates discontinuance when it does. As with didanosine, pancreatitis may also occur but is uncommon. Mouth and oesophageal ulceration

can occur as can disorders of gastrointestinal tract motility. Cardiomyopathy is described. It has been found to be more effective when used in combination with zidovudine than either drug alone [365]. More recently it has been shown to be more effective when used as triple therapy in combination with zidovudine and the protease inhibitor indinavir compared with zidovudine and lamivudine alone [344].

### *Stavudine*

Like zidovudine, stavudine (d4T) is an orally administered thymidine nucleoside analogue that competes with thymidine triphosphate for a nucleoside-binding site on the growing chains of viral DNA being produced by reverse transcriptase; it therefore acts as a 'chain terminator' and prevents reverse transcriptase from making DNA copies of viral genomic RNA. It is well absorbed and about 40% is excreted unchanged in the urine. The usual dose is 40 mg 12-hourly for patients weighing more than 60 kg and 30 mg 12-hourly for those weighing less than 60 kg. The main dose-limiting adverse effect is a painful sensory neuropathy, which is more likely to occur at high doses and in patients with advanced disease. This is ordinarily reversible if the drug is stopped, as are changes in liver function. Stavudine is less toxic to bone marrow than zidovudine, neutropenia occurring in about 5% of patients with less advanced disease. Thrombocytopenia is still less common. Acute pancreatitis may occur but, as with zalcitabine, this is less common than with didanosine. Stavudine is another promising antiretroviral agent whose efficacy has been demonstrated in comparison with zidovudine [366]. Further evaluation in trials of combination chemotherapy are ongoing.

### *Lamivudine*

Lamivudine (3TC) is another relatively new orally administered nucleoside analogue. Like zidovudine it is a reverse transcriptase inhibitor active against HIV-1 and HIV-2. It has good bioavailability. The usual recommended dose is 150 mg 12-hourly. Adverse effects appear to be uncommon with long-term use but, as with other nucleoside analogues, there have been reports of peripheral neuritis and pancreatitis. Headache, nausea, vomiting, diarrhoea, abdominal pain and disturbances of liver enzymes have also been described [367]. The clinical benefit of lamivudine when added to previously available nucleoside analogues has been shown [368], as has its benefit in triple therapy regimens with indinavir and zidovudine [344,345].

### **HIV protease inhibitors**

Members of this newer class of antiretroviral drug inhibit

viral protease by competing with it for its binding site [340]. These drugs, including ritonavir, indinavir, saquinavir, nelfinavir and others [342,343], act on the process of viral replication at a later stage than the reverse transcriptase inhibitors, preventing the cleavage of HIV precursor proteins in infected cells and thereby blocking the maturation of viral particles and impeding further waves of infection. These compounds are used in combination with nucleoside analogues. All of them are inhibitors of the hepatic cytochrome P450 enzyme system, ritonavir being the most potent in this respect, so that great care should be taken to avoid drug interactions and the manufacturers' summaries of product characteristics should be consulted. As an example, ritonavir substantially increases plasma levels of rifabutin (used to treat *Mycobacterium avium-intracellulare* complex) and its metabolites, thereby increasing the risk of uveitis, so that these two drugs should not be used together. Competitive inhibition of terfenadine, astemizole and cisapride may also occur with the risk of cardiac dysrhythmias, including torsades de pointes. The addition of a P450 inhibitor such as ketoconazole may substantially increase the availability of the protease inhibitor, especially in the case of saquinavir [340]. Haemophiliacs receiving protease inhibitors should be warned that they may increase their bleeding tendency. The following drugs belong to this group and others are under development or investigation:

#### ***Ritonavir***

This orally administered protease inhibitor is currently taken in combination with nucleoside analogues at a recommended dose of 600 mg twice daily, preferably with food. The drug is principally metabolized and eliminated by the liver. At the commencement of treatment, nausea, vomiting, abdominal pain and diarrhoea are common and patients should be forewarned [340]. A gradual build-up of the dose is recommended to prevent this and an antiemetic may be necessary. Headache, disturbances of taste and flushing may also be complaints, and circumoral and digital paraesthesiae are not uncommon, usually resolving despite continued treatment. Elevated liver enzyme levels and hypertriglyceridaemia may be found on blood testing but pancreatitis is not a recognized complication. Hyperglycaemia and fat redistribution ('buffalo hump') have been reported. Other adverse effects and a myriad of drug interactions are listed in the summary of product characteristics [340].

#### ***Indinavir***

This orally administered protease inhibitor is currently taken in combination with nucleoside analogues, such as zidovudine and lamivudine, at a recommended dose of

800 mg 8-hourly 1 h before or 2 h after food or with a low-fat snack [344,345]. Metabolism and excretion of the drug is mainly hepatic, only 20% being excreted unchanged or as metabolites in the urine. Gastrointestinal side-effects may occur as for ritonavir. Patients may complain of headache, a dry skin, rashes and taste disturbance. Liver function changes may include hyperbilirubinaemia, which is reversible and occurs in 10% of patients; 3–4% of patients develop renal calculi with loin pain, this being the most important side-effect so that a high fluid intake (at least 1.5 L per 24 h in addition to normal intake) is advised to counter this tendency [340]. Episodes of severe haemolysis have been reported. Hyperglycaemia and fat redistribution ('buffalo hump') have been reported. Other adverse effects are listed in the summary of product characteristics.

#### ***Saquinavir***

This orally administered protease inhibitor with relatively low bioavailability is currently taken in combination with nucleoside analogues at a recommended dose of 600 mg three times daily within 2 hours after a meal [369]. Newer soft gel capsules increase bioavailability but at the price of increased gastrointestinal side-effects. The principal route for metabolism and excretion is the liver. Diarrhoea, nausea, vomiting and abdominal discomfort, oral ulcers and peripheral neuropathy may occur. Minor disturbances of liver function, hyperglycaemia and fat redistribution ('buffalo hump') have been reported. Rifampicin and rifabutin reduce blood levels of saquinavir significantly. Other adverse effects and precautions are listed in the summary of product characteristics.

#### ***Nelfinavir***

This orally administered protease inhibitor has improved bioavailability and is currently taken in combination with nucleoside analogues at a recommended dose of 750 mg three times daily, with or shortly after meals. The principal route of metabolism is the liver. The dose-limiting side-effect is diarrhoea, which can usually be controlled with an ant motility drug such as loperamide. Nausea, vomiting, fatigue and paraesthesiae may all occur. Biochemical abnormalities such as raised serum transaminases, triglyceride and glucose may occur [340].

#### **Other antiviral drugs in HIV infection**

A number of non-nucleoside reverse transcriptase inhibitors are under investigation or in use. These include nevirapine (now licensed in the UK and USA), delavirdine (licensed in the USA), loviride and the investigational non-nucleoside reverse transcriptase inhibitor efavirenz. The field of drug research and development surrounding HIV infection is one of strenuous activity as the search for

effective clinical regimens continues pending the possible development of a vaccine.

### Drugs active in CMV infection

HIV-related research extends beyond the development of antiretroviral drugs to the development of drugs to combat superadded viral infection in AIDS. The following antiviral drugs have so far been shown to be clinically effective in delaying the progression of CMV retinitis, a complication that may affect about 40% of patients with AIDS and with an incidence similar to *Pneumocystis carinii* pneumonia and *Mycobacterium avium* complex infection [370,371].

#### Ganciclovir

Ganciclovir, a nucleoside analogue of guanosine, is structurally related to (but much more toxic than) aciclovir (Fig. 9.13). It is active against herpes viruses and was the first drug shown to be effective against CMV in humans. Infection with CMV is the commonest cause of intraocular infection in AIDS and, if untreated, leads to progressive retinal destruction, with or without retinal detachment, and blindness. It tends to occur in patients with a CD4+ count of less than  $0.05 \times 10^9/L$ .

#### Mode of action

Phosphorylation of ganciclovir takes place by virally produced thymidine kinase, with the formation of ganciclovir monophosphate in cells infected by CMV. Further phosphorylation produces ganciclovir triphosphate, which reaches sufficient concentration in infected cells to inhibit viral DNA polymerases, which in turn prevents the production of new CMV DNA chains and thereby slows viral replication [372]. Ganciclovir triphosphate reaches a much higher concentration in CMV-infected cells than aciclovir triphosphate and also has a longer half-life, accounting for its much improved CMV inhibitory effect [372].

Fig. 9.13 Structure of ganciclovir.

#### Spectrum of activity

Although shown to be active in tissue culture against various herpes viruses, including HSV and VZV, it is much more toxic than aciclovir and its only clinical application has been in the management of CMV infection.

#### Administration, distribution, excretion and dose

Ganciclovir was initially available only as a solution for intravenous infusion, now used for induction and 'salvage' (repeat induction) therapy. Later, an oral preparation became available for maintenance treatment, once the retinitis was considered stable [373], and most recently an intraocular implant has become available [374]. Sub-retinal fluid levels similar to plasma levels are achieved after intravenous administration and the drug crosses the blood-brain barrier. More than 90% of the drug is excreted unchanged by the kidneys and the dose is reduced progressively for estimated creatinine clearances below 70 mL/min.

The intravenous formulation is typically administered for induction by infusion over 1 h at a high dose of 5 mg/kg every 12 h for 2–3 weeks [371]. After intravenous induction therapy, lifelong maintenance doses of 5 mg/kg every 24 h intravenously for 7 days per week or 6 mg/kg for 5 days per week are prescribed. Oral therapy using ganciclovir 1000 mg three times daily (12 capsules per day) is an alternative to parenteral treatment. This formulation may be almost equivalent in its maintenance effect to parenteral treatment, with a much lower incidence of severe neutropenia and no risk of central venous catheter-related sepsis. However, it is very costly and sufficient doubt about relative efficacy remains for it to be usual to prescribe the intravenous formulation, especially for central retinitis which is more likely to cause blindness [371].

More recently, an intraocular ganciclovir-releasing device, which may be implanted as an outpatient procedure, has been developed. This results in higher intravitreal drug levels than those achieved with intravenous therapy. It remains therapeutically active for up to 8 months (but is usually replaced after 6 months), although initial enthusiasm has been tempered by concerns about a possible increased incidence of early retinal detachment and the potential for the development of manifestations of CMV infection in the unimplanted eye and elsewhere in the body [371,372]. Implants may be suitable for patients with central retinitis who have so far retained good vision in the infected eye.

#### Adverse effects

Although many adverse effects have been described, the principal dose-limiting side-effects of ganciclovir are neu-

tropenia and thrombocytopenia. Anaemia may also occur with prolonged treatment but is less common. These side-effects may be summative, particularly during induction, if other marrow-depressing drugs such as zidovudine are used in parallel, so that profound myelosuppression may occur and dose modification is required [372]. It is usual to titrate the dose so that the neutrophil count is in the range  $0.5\text{--}1.0 \times 10^9/\text{L}$  and to treat with a recombinant human granulocyte colony-stimulating factor, such as filgrastim, if the count drops below  $0.5 \times 10^9/\text{L}$ . Ganciclovir should be stopped if the platelet count drops below  $20 \times 10^9/\text{L}$ . Myelosuppressive effects usually reverse within a week of stopping the drug but occasionally fatal bacteraemias have resulted. It is advisable to check the blood count twice weekly during induction and every 1–2 weeks during maintenance treatment. Rises in serum creatinine may be seen with prolonged treatment, so that this should be checked monthly. Intravenous ganciclovir has a tendency to cause local pain and thrombophlebitis at the site of the infusion.

#### *Principal uses in respiratory medicine*

The principal use of ganciclovir is the treatment and control of CMV retinitis in patients with AIDS [372]. Over 80% of patients are expected to respond to intravenous treatment, most lesions stabilizing within 2 weeks and healing within 1 month; 65% of patients have unilateral disease when the retinitis is first detected and treatment prevents involvement of the unaffected eye. However, without treatment most patients become blind or severely visually impaired in the affected eye within 4–6 months, the disease becoming bilateral in 60% [372]. Treatment must be lifelong. CMV resistance to ganciclovir may emerge during treatment, necessitating either an increase in dosage or a switch in therapy to an alternative drug such as foscarnet or cidofovir [371].

Prophylactic oral ganciclovir 1000 mg 8-hourly may be used in an attempt to prevent CMV infection in AIDS patients with a CD4+ count of less than  $0.1 \times 10^9/\text{L}$ , although the limited efficacy of such use has to be set against adverse effects and high cost [372,375]. The drug has also been used prophylactically in CMV-seropositive transplant recipients [372].

Ganciclovir has also been used to treat CMV colitis and polyradiculopathy in patients with AIDS and CMV pneumonia in transplant recipients [372].

#### *Foscarnet*

Foscarnet is an intravenously administered inorganic pyrophosphate analogue that directly inhibits the activity of viral DNA polymerase, an enzyme essential for the replication of CMV. It also has a weak antiretroviral effect by inhibiting HIV reverse transcriptase, an observation

that may have accounted for a small but significant survival advantage (8.5–12.6 months) in a comparative CMV retinitis trial with ganciclovir [376]. Its spectrum of activity covers most ganciclovir-resistant CMV and also aciclovir-resistant HSV and VZV strains. Over 80% of the drug is excreted unchanged by the kidney so that progressive dose reductions have to be made in renal insufficiency.

The principal dose-limiting adverse effect is nephrotoxicity, an increase in serum creatinine occurring after the first week of treatment in about half of patients. Numerous other side-effects have been recorded, including paraesthesiae, headache, nausea and tetany, which may result from the drug's ability to transiently chelate ionized calcium during infusion, the rate of which should therefore be carefully regulated. There may also be disturbances of phosphate, potassium and magnesium so that it is recommended that monitoring should include serum creatinine, calcium, phosphate and potassium twice weekly during induction and once weekly thereafter [371]. Genital ulceration may occur and, as with ganciclovir, there is a risk of central venous catheter-related sepsis.

Foscarnet is significantly more costly than ganciclovir and is diluted according to the manufacturer's instructions and infused by pump over 2 h at a usual induction dose of 90 mg/kg every 12 h for 2 weeks in those with normal renal function. The maintenance dose is 90 mg/kg as a single daily infusion. Treatment must be lifelong. As with ganciclovir, resistant CMV mutants may emerge during treatment.

Although mainly used to treat CMV retinitis [371], foscarnet may also be effective in the treatment of aciclovir-unresponsive serious HSV and VZV infections.

#### *Cidofovir*

Cidofovir is an intravenously administered nucleoside phosphate analogue of cytosine that undergoes intracellular phosphorylation to cidofovir diphosphate, resulting in viral DNA polymerase inhibition and thereby slowing down the synthesis of viral DNA. In contrast to ganciclovir and aciclovir, this phosphorylation is dependent on host rather than viral enzymes.

It has been shown to be active *in vitro* against a number of herpes viruses, including HSV-1 and HSV-2, VZV and CMV. It has also been shown to be effective *in vivo* against CMV and to delay the progression of CMV retinitis in patients with AIDS [377]. It is currently licensed for the treatment of CMV retinitis in patients with AIDS without significant renal dysfunction (see below) and in whom other agents are considered unsuitable.

The active intracellular metabolites of cidofovir have unusually long half-lives, up to 65 h for the diphosphate, so that the compound has a prolonged antiviral effect and

needs administration at 1–2 weekly intervals. This is clearly more convenient than daily infusions of ganciclovir or foscarnet and obviates the need for indwelling catheters.

The major side-effect is dose-dependent nephrotoxicity with the risk of renal tubular necrosis. The chance of this may be reduced by prehydration and concomitant administration of high-dose probenecid, which competes with cidofovir for uptake in the proximal renal tubules. The recommended dose of cidofovir for induction is 5 mg/kg infused at a constant rate over 1 h once per week for two consecutive weeks; for maintenance, the same dose is given once every 2 weeks. To reduce the potential for nephrotoxicity, 1 L of normal saline is infused over 1 h prior to dosing and 2 g probenecid is taken orally 2 h before commencement of the infusion and 1 g taken 2 and 8 h after completion of the infusion, to a total of 4 g. A further litre of saline may be given during or after the cidofovir infusion. Probenecid itself may cause nausea, fever and rashes. Cidofovir is presently contraindicated in patients with pre-existing renal impairment, defined as serum creatinine greater than 133  $\mu\text{mol/L}$  (>1.5 mg/dL) or creatinine clearance less than 55 mL/min or proteinuria greater than 100 mg/dL (2+ or more by dipstick). Cidofovir should not be used with other nephrotoxic drugs. It may interfere with the renal tubular excretion of many drugs and the manufacturer's summary of product characteristics should be consulted before use.

The efficacy of cidofovir is probably similar to that achieved by standard intravenous ganciclovir or foscarnet but long-term treatment may be limited by toxicity [371]. As with ganciclovir and foscarnet, resistant CMV mutants may emerge during treatment.

### Combined therapy for CMV infection

A combination of standard-dose ganciclovir and foscarnet for CMV retinitis was found to be more effective in delaying disease progression than high doses of either drug alone but there was a higher patient fall-out from the combined regimen as a result of drug intolerance [378]. Other trials of combined therapy are likely to be published and further anti-CMV drugs, such as a valine ester of ganciclovir, are under development.

## Antiviral agents in influenza prophylaxis

### Adamantanes: amantadine and rimantadine

Amantadine (Fig. 9.14) is a crystalline primary amine and has long been in use as an antiparkinsonian drug. It is also known to have some activity against influenza A virus infection. Rimantadine (Fig. 9.14) is a closely related derivative, having an additional methyl group attached to the

Fig. 9.14 Structure of (a) amantadine hydrochloride and (b) rimantadine hydrochloride.

same cage-like structure. Amantadine and rimantadine have no activity against influenza B virus, which accounts for about 35% of all cases. Rimantadine is not generally available in the UK

### Mode of action

Both drugs are thought to act at low concentrations at an early stage of replication by blocking the ion channel function of a viral structural protein and preventing the uncoating of virus particles [379,380]. Although the drugs have weak *in vitro* activity against some other viruses, including rubella, parainfluenza and respiratory syncytial viruses, their only practical use is against influenza A virus.

### Administration, distribution and excretion

The drugs are well absorbed after oral administration and are widely distributed. The mean half-life of amantadine is about 15 h but may vary widely between patients. It is excreted unchanged in the urine, so that accumulation tends to occur in renal failure and dose reduction is necessary for significantly reduced creatinine clearances, according to the manufacturer's instructions. Rimantadine mainly undergoes hepatic metabolism so that dosage reductions only need be made in liver disease or severe renal failure (creatinine clearance <10 mL/min). It has an even longer half-life than amantadine of about 30 h.

### Dosage

Amantadine may be used at a dose of 100 mg daily for influenza prophylaxis in 'at-risk' unimmunized people for as long as protection is required (usually about 6 weeks) or for 2–3 weeks following immunization to allow the vaccine to take effect. Half this dose may be used in patients over the age of 65 years by giving the same dose every second day. Some authorities recommend twice these dosages [381]. Reduced doses should also be given in renal insufficiency according to the creatinine clearance [379,380]. A recommended dosage schedule for rimanta-

dine prophylaxis is 100 mg twice daily, reducing to 100 mg daily in elderly nursing home residents [382].

#### *Adverse effects*

Adverse effects are few and are dose related, although particular care needs to be taken in patients with renal insufficiency and in the elderly [383,384]. CNS side-effects have been recorded, particularly in the elderly, and may include dizziness, lethargy, insomnia, headaches, anxiety and depression; if high blood levels are allowed to develop, toxic psychoses may occur. Livedo reticularis may rarely occur. Amantadine is contraindicated in epilepsy as patients may have their seizure tendency enhanced [385]. Rimantadine has been reported to have fewer CNS side-effects [380,386].

#### *Principal uses in respiratory medicine*

Early studies of prophylactic amantadine showed that the drug could reduce the incidence of influenza A infection or diminish the symptoms of those who developed infection when taking the drug [387–389]. Amantadine (100–200 mg daily) has also been used in the treatment of influenza A and has been shown to reduce the duration of fever by 1–2 days if started within the first 48 h of symptoms [390,391].

There are obvious difficulties in making a clinical diagnosis of influenza in view of the similar symptoms that may be produced by other community-acquired respiratory viral infections; furthermore, the drug has been shown to be useful only in influenza A infection and not in influenza B [392]. Although the widespread use of amantadine has been recommended, it is probably best reserved for occasions when there is known to be a high prevalence of influenza A infection in the community. In the UK, this is indicated by Public Health Laboratory Service reports of isolation of influenza A virus and by clinical returns collated by the Birmingham research unit of the Royal College of General Practitioners. Amantadine (or rimantadine) may be used in influenza A virus infection in the following situations.

**1** Prophylactically for those at particular risk, such as unvaccinated persons living in a home or institution in which influenza has already broken out (postexposure prophylaxis), particularly the elderly and those with chronic debilitating illnesses [393]. Such people should be vaccinated but may also be given amantadine for at least 2 weeks while the vaccine takes effect. In such situations, these drugs are about as effective as influenza vaccination. They should not be regarded as a substitute for vaccination and do not interfere with the immune response to influenza vaccines.

**2** Prophylactically for unvaccinated healthcare workers

and other key personnel during epidemics in order to prevent disruption of the services that they provide.

**3** As treatment in patients in whom a clinical diagnosis of influenza has been made, particularly those in whom complications might be expected to occur such as the elderly or those with chronic cardiac or respiratory disease [394,395]. It is reasonable to treat for up to 1 week in such circumstances. It is unwise to use these drugs for both postexposure prophylaxis and treatment in the same home as the selection and transmission of resistant influenza A virus may occur [385].

Amantadine and rimantadine are broadly similar both structurally and in their mechanism of action. Both are about as effective as available vaccines in preventing influenza A virus infections and when used as treatment shorten the illness by about a day.

#### *Zanamivir: a drug for influenza A and B virus infections*

Zanamivir is a sialic acid analogue that selectively inhibits both influenza A and B virus neuraminidases (sialidases) [396]. These enzymes are essential in allowing the virus to attack the host cell surface, thereby permitting the release of virus particles from infected cells. The drug is currently undergoing clinical investigation and has recently become available for clinical use. It has been administered topically as a dry powder both to the nasal passages and by inhalation and has been shown (i) to protect adults from developing illness when experimentally infected with influenza A virus [397] and (ii) to reduce the duration of illness of naturally acquired influenza (both types A and B) by 1–2 days when used as antiviral treatment within 48 h of the patient becoming symptomatic [398]. It is available as a metered dose dry powder oral inhalation to be taken at a dose of 5 mg twice daily for 5 days. Studies have been carried out in otherwise healthy patients with influenza and beneficial effects in more vulnerable groups have yet to be shown. There are as yet no comparative trials of amantadanes and zanamivir. Other neuraminidase inhibitors, some of which may be administered orally, are also at early stages of investigation [396].

#### **Other antiviral agents**

Numerous other antiviral substances are being investigated under laboratory conditions or are being applied to clinical situations with varying degrees of success.

*Interferons* are a group of naturally produced glycoproteins that are important in host cellular defences against viral infection. They are active *in vitro* against a variety of DNA and RNA viruses, as well as showing some antitumour effects. Three major types are recognized ( $\alpha$ ,  $\beta$  and  $\gamma$ ), of which interferon  $\alpha$  has received the most attention. They have their effect indirectly by inducing other

antiviral enzymes and by modifying and stimulating the host's immune responses. Large quantities may now be produced by bacterial and yeast clones of interferon genes as a result of advances in recombinant DNA technology. They have been used, with some success, as a topical nasal spray to prevent rhinovirus infections, and have also been given in parenteral form with moderate success for virus infection in immunocompromised hosts, e.g. VZV in children [390,399]. Side-effects of systemic therapy include flu-like symptoms, with myalgia and fever, and also marrow toxicity [400].

*Tribavirin* (ribavirin) is an antiviral nucleoside that is available for use as a small particle aerosol in the treatment of respiratory syncytial virus bronchiolitis and pneumonia in infants, being thought to accelerate clinical recovery in this situation [401]. This drug is now available in the UK for the treatment of infants and young children with severe respiratory syncytial virus bronchiolitis.

## Drugs used in the management of airflow limitation

### Sympathomimetic bronchodilators

Sympathomimetic bronchodilators [402] have been in use for several thousand years, an ephedrine-containing extract derived from the plant *Ephedra equisetina* having been used in ancient China. Modern sympathomimetics (syn. adrenoceptor stimulants, adrenergic receptor agonists), as used in the treatment of asthma, are synthetic derivatives, or analogues, based on the structure of epinephrine (adrenaline). This naturally occurring catecholamine is both an  $\alpha$ - and  $\beta$ -adrenergic agonist that acts as a neurotransmitter in the sympathetic nervous system,  $\alpha$  receptors being predominantly stimulatory (vasoconstriction) and  $\beta$  receptors predominantly inhibitory (relaxation of smooth muscle in the respiratory tract, vasculature and uterus) [403]. Epinephrine was used as a bronchodilator for a large part of the twentieth century until it became obsolete as a result of the development of isoprenaline (USA, isoproterenol), which stimulates only  $\beta$ -adrenergic receptors. Isoprenaline itself largely fell from use (and is no longer easily obtainable in the UK) following the discovery that  $\beta$ -adrenergic receptors could be divided into types 1 and 2 and with the development of more selective  $\beta$ -adrenergic receptor agonists (or  $\beta$  agonists), the effects of which are directed more specifically to the  $\beta_2$  receptors, which produce bronchodilatation (as well as vasodilatation), and less to  $\beta_1$  receptors that stimulate heart muscle [404]. In skeletal muscle,  $\beta_2$  stimulation is responsible for the tremor that is a common unwanted effect of  $\beta$ -agonist bronchodilator use.

A common biochemical feature shared by the majority of the sympathomimetic bronchodilators is the possession of a six-carbon (or benzene) ring with an ethanolamine

side-chain in the C-1 position. Various substitutions can be made at the C-3, C-4 and C-5 positions on the ring and at positions  $R_1$  and  $R_2$  on the side-chain (Fig. 9.15). These substitutions affect the properties of an individual group member, such as its potency, selectivity, duration of action and metabolic fate. Three groups of sympathomimetic bronchodilator have been described on the basis of their closely related chemical structures: catecholamines (e.g. epinephrine, ephedrine, isoprenaline, rimeterol), saligenins (e.g. salbutamol, salmeterol) and resorcinols (e.g. terbutaline and fenoterol, which was derived from orciprenaline). Eformoterol (formoterol) is classed as an *N*-arylalkylamine, having a formamide group at the C-3 position of the benzene ring and an *N*-arylalkyl side-chain (Fig. 9.16). The molecular structures of epinephrine, salbutamol (USA, albuterol), terbutaline, isoprenaline and orciprenaline (USA, metaproterenol) are shown in Figs 9.17–9.20. The similarities are striking and such is the case with most of the sympathomimetic bronchodilators in current use.

#### Selectivity

Table 9.6 lists some of the sympathomimetic bronchodilators presently available. Those in the first column have been shown to be more selective  $\beta_2$  agonists, although concerns have been expressed about fenoterol in this regard. Those in the second column, although effective bronchodilators to varying degrees, are non-selective or poorly selective and are more likely to produce unwanted effects. As a general rule, the larger the substitution at the  $R_2$  position on the side-chain, the greater the selectivity displayed by the drug (Figs 9.17–9.20). This also accounts in part for the relative non- $\beta_2$  selectivity of orciprenaline, which has the same  $R_2$  substitution as isoprenaline and is therefore

Fig. 9.15 Sympathomimetic bronchodilators: common benzene ring and ethanolamine side-chain (see text).

Fig. 9.16 Structure of (a) eformoterol and (b) salmeterol.

Fig. 9.18 Structure of salbutamol (albuterol).

Fig. 9.19 Structure of terbutaline.

also more apt to cause direct cardiac stimulation if standard doses are exceeded [405].

It should be noted that  $\beta_2$  selectivity diminishes as dose increases, so that a high plasma level following oral, inhaled or particularly intravenous dosage produces cardiac stimulation with tachycardia. However, such effects do not occur following standard inhaled doses using a metered-dose inhaler (MDI) [406].

#### Duration of action

The older catecholamine bronchodilators like epinephrine (adrenaline) and isoprenaline are degraded enzymatically by catechol-*O*-methyltransferase and are relatively short-acting, their bronchodilator effect lasting 1–3 h after inhalation. Movement of the hydroxyl groups from the C-3,C-4 configuration on the catechol nucleus (Fig. 9.15) to the C-3,C-5 configuration on the resorcinol nucleus produces the intermediate duration of action (3–6 h) seen with orciprenaline, terbutaline and fenoterol (Figs 9.17–9.20). The substitution at the C-3 position also accounts for the intermediate duration of action of the saligenin salbutamol (4–6 h). These more selective  $\beta_2$  agonists have a slightly slower onset of action than isoprenaline. Two  $\beta_2$  agonists have a duration of action that exceeds 12 h, salmeterol and eformoterol (Fig. 9.16). Each compound has an extended side-chain and is highly lipophilic. It has been postulated that the long lipophilic side-chain of the salmeterol molecule anchors it to an 'exo-site' in close proximity to the active  $\beta$ -receptor site in such a way that prolonged

‡ not available in UK

activation by the saligenin head takes place. However, this has been questioned and it has been proposed that both salmeterol and eformoterol interact with, and are gradually released from, the cell membrane lipid bilayer (plasmalemma) over a prolonged period [407,408]. The speed of onset of action of eformoterol is similar to that for salbutamol, with peak bronchodilatation occurring at about 30 min, whereas salmeterol is slower, taking 1–2 h to achieve its maximal effect [409,410].

#### Mode of action

The  $\beta$  agonists produce bronchodilatation by stimulating  $\beta_2$  receptors situated in the smooth muscle of the bronchial tree, from the trachea down to the terminal bronchioles. This activates the enzyme adenyl cyclase [411], facilitating the conversion of ATP to cyclic AMP and resulting in the relaxation of smooth muscle in the bronchial wall. The cellular chemistry is complex but probably involves the activation of protein kinase with a reduction in ionic calcium concentration in bronchial smooth muscle [412]. Other potentially beneficial non-bronchodilator  $\beta_2$  effects include enhanced mucociliary transport, diminished

release of histamine and other chemical mediators of asthma from mast cells, inhibition of cholinergic neurotransmission and a possible increased ventilatory response to hypercapnia and hypoxia [407,413–416]. As a consequence of  $\beta$ -agonist activity, bronchoconstriction in response to both allergen challenge and exercise is reduced and the effect of corticosteroids tends to be potentiated [417,418]. Small increases in bronchial reactivity may be seen after the bronchodilating effect of  $\beta$  agonists has worn off [419,420]. It has not been possible to gauge the clinical significance of this but there is the theoretical risk of a serious asthmatic reaction to a given trigger factor in a patient whose airways are already hyperreactive [421]; this might be a particular concern in patients with labile asthma who were relying too heavily on  $\beta$ -agonist therapy and complying poorly with inhaled steroid treatment. All the  $\beta_2$  agonists currently available are racemic mixtures containing stereoisomers (enantiomers) of the same molecule. Research is currently ongoing to see if specific pharmacological effects can be related to individual stereoisomers, which if produced commercially in pure form might select desirable qualities and dispense with undesirable ones [422].

Regularly taken, long-acting  $\beta_2$  agonists do not have any significant anti-inflammatory actions and should not be used as substitutes for inhaled steroids.

### Potency

The potency of sympathomimetic bronchodilators can be expressed in terms of  $ED_{50}$ , i.e. the dose that produces a standard measured effect in 50% of subjects; the lower the  $ED_{50}$ , the greater the potency. Although the potency of the  $\beta_2$  agonists in Table 9.6 may vary according to the configuration of the chemical substitutions in the benzene ring and ethanolamide side-chain, this is of little practical consequence since the dose contained in one 'puff' of MDI 'A' is manipulated by the manufacturer to achieve the same effect as one 'puff' of a lesser dose of a slightly more potent compound 'B'. The same applies to tablet formulations: a 4-mg tablet of salbutamol is equipotent to a 5-mg tablet of terbutaline and 400  $\mu$ g of salbutamol by MDI is for practical purposes equipotent to 500  $\mu$ g of terbutaline. The discrepancy is much greater for eformoterol, the usual dose of which is only 12  $\mu$ g.

Although prolonged use of  $\beta$  agonists may lead to some  $\beta_2$ -receptor downregulation, there is no convincing evidence that tolerance (subsensitivity or tachyphylaxis) develops to the extent of presenting a significant clinical problem [407,423–428]. Tolerance to muscle tremor, increased heart rate and other systemic adverse effects has been observed [429,430].

Bronchodilatation following an oral or parenteral dose of  $\beta_2$  agonist is a function of the plasma level achieved, whereas this is not the case following an inhaled dose.

This has obvious and important implications for avoiding the tiresome systemic side-effects by inhaled rather than systemic administration of the drug [431].

### Administration

*Inhalation.* The  $\beta_2$  agonists may be taken in a variety of ways but the preferred route is inhalation from an MDI. About 10% of the fraction leaving the device reaches the lungs, the remainder impacting in the oropharynx and being swallowed. These small quantities nevertheless quickly (depending on the drug used) produce the desired bronchodilator effect in a responsive patient and although absorbed from the lungs, systemic side-effects are generally insignificant by comparison with an orally administered drug because of the microgram quantities involved. One of the principal disadvantages of this method is that it requires a modicum of coordination on the part of the patient, each dose being ideally inhaled from about functional residual capacity by a slow inspiratory manoeuvre with a breath-hold to the count of 10 at total lung capacity. The very young and the very old may not possess the necessary neuromuscular coordination to achieve this with conventional 'press and breath' inhaler devices, and arthritis or severe dyspnoea may also prevent proper administration by this route. Various methods have been devised to escape these difficulties: the inhalation of dry powder preparations; the use of 'spacer' devices of various shapes and sizes; the use of breath-actuated MDIs; and administration of drugs by wet nebulized aerosol. The last method of administration has become the standard method of bronchodilator delivery for patients with attacks of acute severe asthma, usually being as effective as parenteral therapy [432]. Used on a regular basis at home, compressed air nebulizers delivering  $\beta$  agonists and antimuscarinic bronchodilators are often popular with patients who have severe COPD, although objective evidence that they are more effective than MDIs is hard to come by, particularly if the latter are used with spacer devices [433–435]. These matters have been reviewed in detail elsewhere [436,437].

Inhaled therapy has the advantage of a rapid onset of action compared with the same drug taken orally; thus the inhaled non-catecholamine  $\beta_2$  agonists bronchodilate within 3–6 min, achieving 80% bronchodilatation in 5 min and reaching a peak in 30–60 min, with the effect wearing off over about 3–6 h. Those inhaled bronchodilators belonging to the catecholamine group, such as epinephrine (adrenaline) and isoprenaline have an even more rapid onset of action, bronchodilating within 1–3 min and peaking at about 5 min, so that isoprenaline has been useful in the lung function laboratory. However, their duration of action is shorter, so that their effect lasts for only 1–3 h. The only  $\beta_2$ -selective bronchodilator belonging to the catecholamine group was rimeterol and this shared the group

characteristic of being shorter-acting than the other  $\beta_2$  agonists, which are all non-catecholamines. However, it is no longer generally available. The rapidity of onset of isoprenaline and even epinephrine may account in part for the reluctance of the diminishing band of long-standing asthmatics, settled onto older bronchodilator preparations, to switch to newer and more selective  $\beta_2$  stimulants such as salbutamol, the onset of action of which is not quite so rapid. It used to be worth trying the effect of the selective catecholamine rimeterol (no longer available in the UK) in such patients. Another possible reason for the failure to achieve such a change in therapy is the CNS stimulating effect of some of the earlier unselective bronchodilators.

*Oral medication.* A very small proportion of patients need to take their sympathomimetic bronchodilator medication orally because of their inability to manage inhaled therapy. Oral medication has a slow onset of action, producing bronchodilatation after about 30 min and reaching a peak at 1–2 h. The plasma half-lives of some  $\beta_2$  agonists that are adequately absorbed from the gut and available in oral form are shown in Table 9.7. It should be noticed that terbutaline and fenoterol have relatively long half-lives so that twice-daily dosage may be adequate in some patients and this might be an advantage with regard to compliance. Fenoterol is not available as an oral preparation in the UK. Oral formulations of catecholamines such as isoprenaline are inadvisable as they undergo gastrointestinal inactivation by monoamine oxidase. The only exception is ephedrine but the non-selectivity and low potency of this drug argue against its use in modern practice.

Controlled-release oral formulations of terbutaline (7.5 mg) and salbutamol (8 mg) exist [438]. When taken on retiring at night, these sometimes prove to be a useful supplement to regular inhaled  $\beta_2$ -agonist and corticosteroid therapy in patients who continue to experience nocturnal symptoms despite optimal adjustment of their other therapy [439], alternatives being eformoterol, salmeterol and sustained-release theophylline. Bambuterol is a prodrug of terbutaline, with activity spanning 24 h; taken as a once-daily dose of 20 mg at night it may produce similar bronchodilatation to 5 mg terbutaline (standard release) three times daily [440] and may also be useful in nocturnal asthma [441].

*Parenteral medication.* The  $\beta_2$  agonists salbutamol and terbutaline are both available for parenteral administration in severe exacerbations of asthma. Both compounds behave similarly when administered by these routes. The onset of action is rapid, occurring within a few minutes, and the peak effect reached sooner than by inhalation, the duration of action being about 4 h [431]. Subcutaneous  $\beta_2$  agonists have also been given by continuous infusion at doses of 1–12 mg terbutaline per 24 h in ambulant but brittle severe asthmatics using small, portable, battery-powered mechanical pumps (e.g. Graseby MS26) connected to a short 25-gauge ‘butterfly’ needle, or by four equally divided injections spread over 24 h [442–445]. This continuous ambulatory method of administration has been found to be less successful in patients with chronic, severe, systemic steroid-dependent non-variable asthma [443]. The most rapid onset of action follows intravenous administration by slow bolus, followed, if required, by intravenous infusion (Table 9.8). The general clinical experience is that most patients with attacks of acute severe asthma respond as well to nebulized bronchodilator as to the same bronchodilator when given parenterally [432]. However, some patients with acute severe asthma who have a poor response to nebulized bronchodilator, possibly as a result of bronchial plugging, nevertheless respond to a parenteral  $\beta_2$  agonist [446].

Metabolism and excretion

Selective  $\beta_2$  agonists, if swallowed, may undergo some conjugation in the gut wall as well as in liver. Most are relatively resistant to metabolism by catechol-O-methyl-transferase, the enzyme that together with monoamine oxidase account for the shorter duration of action of members of the catecholamine group, such as epinephrine, isoprenaline and rimeterol. Those that are administered parenterally initially circulate in the plasma largely unchanged. Inhaled drugs also enter the circulation, but usually only in microgram quantities. Relatively small quantities of these drugs are excreted unchanged by the kidneys and dosage modification is unnecessary in renal insufficiency. They may slightly penetrate the blood–brain barrier and also cross the placenta so that oral medication is perhaps better avoided in pregnancy, although there is

Table 9.7 Oral  $\beta_2$ -sympathomimetic bronchodilators.

	Plasma half-life (h)	Usual oral dose	Tablet/capsule size (mg)
Salbutamol	4	4 mg t.d.s.–q.d.s.	2, 4
Terbutaline	11	5 mg b.d.–t.d.s.	5 (scored)
Orciprenaline	2	10–20 mg q.d.s.	20 (scored)
Fenoterol*	7	2.5–7.5 mg b.d.–t.d.s.	2.5

\* Not available in UK.  
Smaller doses may be needed in the elderly.

**Table 9.8** Parenteral  $\beta_2$ -sympathomimetic bronchodilators.

	s.c. bolus	i.v. bolus	i.v. infusion
Terbutaline	250–500 $\mu$ g	250–500 $\mu$ g	1.5–5 $\mu$ g/min
Salbutamol	500 $\mu$ g	250 $\mu$ g	5 $\mu$ g/min initially, then 3–20 $\mu$ g/min

For subcutaneous infusion, see text.

no evidence that administration of  $\beta_2$  agonists by MDI in this situation is harmful [447].

*Adverse effects*

The principal dose-limiting adverse effect of the selective  $\beta$ -agonist drugs is skeletal muscle tremor, particularly affecting the hands [448]. This is a consequence of  $\beta_2$ -receptor stimulation in skeletal muscle and is most commonly encountered following oral medication or high-dose inhaled therapy. It is seldom a problem with conventional quantities taken by MDI. Other problems that might arise with forms of administration producing high blood levels are muscle cramps and tachycardia, although serious dysrhythmias are rare. With the selective ( $\beta_2$ ) agonists, tachycardia is thought to be mainly a consequence of reduced peripheral vascular resistance, vasodilatation occurring as a result of the stimulation of receptors in vascular smooth muscle [449], although direct cardiac stimulation may occur as a result of some cardiac  $\beta_2$  receptors [407]. Patients who develop a tachycardia may feel generally unwell, with sweating, light-headedness and headache. Prolonged headache may be an occasional reason for patients refusing to take the long-acting  $\beta_2$  agonists salmeterol and eformoterol. Pre-existing angina pectoris may be aggravated, although this is seldom a practical problem [450]. Short-term metabolic effects of intravenous dosage include hypokalaemia, probably brought about by stimulation of pancreatic  $\beta_2$  receptors, resulting in increased insulin release and an intracellular potassium shift [451]. These adverse effects have led some to recommend that the plasma potassium and ECG should be monitored when intravenous  $\beta_2$  agonists are used in the treatment of asthma [452]. Similar fears have been voiced regarding large doses of nebulized  $\beta_2$  agonists [453], although these metabolic responses diminish with regular administration [454]. Non-specific effects of inhalation include dryness of the mouth, nausea, vomiting and gagging, but these are unusual. There have been a number of reports of paradoxical bronchoconstriction occurring after patients have taken  $\beta$  agonists by pressurized MDI or nebulization [455–457]. Such happenings, which are unusual, may be caused by the drug itself, some constituent of the propellant or its physical characteristics (pH, osmolality, temperature) [455–458]. It has been

pointed out that the potential exists for  $\beta_2$  agonists to worsen ventilation–perfusion mismatch in the short term. This may arise if pulmonary vessels that were previously reflexly constricted in response to local hypoxia are dilated by  $\beta_2$ -receptor stimulation so that blood is shunted into areas of lung still relatively poorly ventilated [459]. In cases where this might matter, this problem should be overcome by the administration of oxygen as a routine. The  $\beta_2$  agonists are uterine relaxants and have been used to prevent premature labour. In connection with this, profuse uterine bleeding has been reported in an asthmatic woman taking salbutamol prior to a termination of pregnancy [460]. Urinary retention is a largely theoretical risk but may occur if high blood levels are achieved in men with prostatic hypertrophy. Local dermal collagen necrosis may occur with prolonged subcutaneous administration of terbutaline [445].

*Asthma deaths and  $\beta$  agonists*

Non-selective adrenergic drugs (see Table 9.6) are more likely to cause cardiovascular side-effects than the  $\beta_2$ -selective preparations and wariness about  $\beta$ -agonist use in general has grumbled on since the retrospective association, made in a number of countries including the UK, New Zealand and Australia, between the asthma death epidemics of the 1960s and the widespread use at that time of a high-dose formulation (Medihaler Iso Forte) of the non-selective  $\beta$ -agonist isoprenaline, which contained five times the standard isoprenaline (Medihaler Iso) metered dosage (120  $\mu$ g) [461].

A similar epidemic of asthma deaths commencing in the mid-1970s was noted in New Zealand and was temporally linked by case–control studies with fenoterol, a  $\beta$  agonist that at the time was marketed only in a high-dose (200  $\mu$ g/puff) device [462]. Semantic argument continues as to whether this increased mortality was a consequence of the particular pharmacological properties of fenoterol itself or whether it represented a class effect that might arise from the excessive use of  $\beta$  agonists in general [463,464]. Discussion also continues about whether the subsequent decline in asthma mortality following the withdrawal of fenoterol as a prescription medicine in New Zealand in 1989 was a consequence of that action or of other variables, such as increased inhaled steroid use [465]. This decline in mortality occurred despite the sales of other  $\beta$  agonists continuing to increase, and no bronchodilators other than high-dose isoprenaline and fenoterol have been epidemiologically associated with increased asthma death rates. High doses of inhaled fenoterol in normal subjects have been shown to increase regional differences in myocardial repolarization as measured by the surface ECG interlead variability in corrected QT interval (so-called QTc dispersion) and it has been postulated that this might predispose to cardiac dysrhythmias, particularly in the presence of

hypoxia [466]. No significant differences in  $\beta_1/\beta_2$  receptor selectivity have been demonstrated between salbutamol and fenoterol in normal subjects [467], although fenoterol has been shown to be more potent on a microgram-for-microgram basis with regard to the production of systemic effects, such as hypokalaemia, muscle tremor and increase in heart rate, but not with regard to bronchodilator response, which is similar in the two drugs [468,469]. These observations are supported by *in vitro* data showing that fenoterol is a full agonist and is more potent on cardiac  $\beta_2$  receptors than salbutamol, which is a partial agonist [470]. The circumstantial evidence is strong that overuse of high-dose fenoterol in acute severe asthma in the 1970s and beyond carried with it a similar risk to that ascribed to high-dose isoprenaline in the 1960s [471].

A recent small case-control study found that patients admitted to intensive care units with attacks of asthma were more than twice as likely to be taking salmeterol than asthmatic patients admitted to ordinary hospital wards. However, it seems that this apparent association was discovered because (i) these patients had more severe asthma in the first place and were thus prescribed salmeterol and (ii) they were more likely to have severe exacerbations, these two variables not being causally connected [472,473].

With regard to the indisputably unselective agents, both epinephrine (adrenaline) and ephedrine may produce strong CNS stimulatory effects as well as peripheral effects such as pallor, tremor, palpitations and urinary retention. A study comparing 0.5 mg subcutaneous epinephrine with the same dose of subcutaneous terbutaline nevertheless found epinephrine to be equally effective and without serious side-effects in a small group of patients treated for acute severe asthma [474].

#### Dosage

The dosages of various  $\beta_2$  agonists are given in Tables 9.7–9.9. With the exception of the long-acting  $\beta$  agonists eformoterol and salmeterol, it is current practice to recommend that  $\beta_2$  agonists taken by MDI in asthma should be used 'as needed' rather than on a regular basis [475,476]. When peak expiratory flow was used as the main outcome measure, control of asthma was equally effective in a group of mild asthmatics, taking only  $\beta_2$ -agonist therapy, when salbutamol was taken 'as needed' rather than regularly [477]. The dose of epinephrine (adrenaline) in anaphylaxis is given below.

#### Principal uses in respiratory medicine

The clinical applications of  $\beta_2$  agonists and other bronchodilators are discussed in Chapters 23 and 35. It should be noted that in addition to relieving wheeze, they may be used to prevent or reduce it in patients with exercise-

**Table 9.9** Doses of inhaled  $\beta_2$ -sympathomimetic bronchodilators by metered-dose inhaler (MDI) and as nebulizer solution.

	MDI (1–2 puffs)	Nebulizer solution
Salbutamol	100–200 $\mu$ g	2.5–5 mg
Terbutaline	250–500 $\mu$ g	5–10 mg
Fenoterol	100–200 $\mu$ g	–
Reproterol	500–1000 $\mu$ g	–
Pirbuterol*	200–400 $\mu$ g	–

\*Not available in UK.

induced asthma [478]. This also applies to the long-acting  $\beta_2$  agonists eformoterol and salmeterol, eformoterol having a more rapid onset of action (see p. 245) [478–480]. These long-acting bronchodilators may also be useful as a single dose before bedtime for patients who continue to experience nocturnal wheeze despite otherwise optimal treatment, as an alternative to an oral sustained-release  $\beta_2$  agonist. The non-selective sympathomimetic agent epinephrine (adrenaline) is the drug of choice for treating anaphylaxis [481]. This may occur in a sensitized person following a bee or wasp sting, following a drug or after the administration of radiographic contrast medium. Epinephrine should be given to patients who develop bronchospasm, serious upper airway narrowing or hypotension with collapse. The dose is 3–5 mL of 1:10000 epinephrine intravenously if this route is accessible. If venous access cannot be achieved or if self-injection is used, then 0.3–0.5 mL of 1:1000 epinephrine is given subcutaneously or intramuscularly and is repeated after 15 min as required, since in severe anaphylaxis epinephrine by any parenteral route is better than none. About 10% of patients may require a second injection. Prompt treatment is usually met with a gratifying response, whereas delay may result in a fatal outcome.

#### Anticholinergic bronchodilators

The potential usefulness of anticholinergic drugs in the treatment of wheeze has long been recognized. Strümpell in the nineteenth century, while mentioning the beneficial effects of atropine and belladonna, stated that the 'stramomium cigarettes to be had in most drug stores are much praised' [482]. Stramomium, an atropine-related substance, is found in the leaves of the plant *Datura stramonium*. A major problem with atropine as a bronchodilator is its ability to cross the blood-brain barrier, with adverse neurological consequences such as restlessness, confusion, hallucinations, etc. With the availability of  $\beta$  agonists such remedies received little attention in modern times until the development of less-soluble synthetic quaternary ammonium analogues of atropine that could be taken by inhalation and which had fewer side-effects than the parent compound. The structures of

**Fig. 9.21** Structure of (a) tertiary ammonium compound atropine and (b) its quaternary ammonium derivative ipratropium bromide.

the synthetic substance ipratropium bromide and of the parent tertiary ammonium compound atropine are shown in Fig. 9.21 in order to illustrate the similarities between the two.

### *Ipratropium bromide and oxitropium bromide*

#### *Mode of action*

Atropine-like bronchodilators are anticholinergic, being competitive antagonists of acetylcholine, the neurotransmitter released at the effector surfaces of the parasympathetic vagal nerve endings. Acetylcholine acts on muscarinic (or smooth muscle) receptors situated in the airways causing bronchoconstriction and mucous secretion. Anticholinergic bronchodilators therefore oppose this action and result in smooth muscle relaxation within the airways, leading to bronchodilatation.

Experimental work has shown that electrical stimulation of the vagi produces mucous secretion and airway narrowing from the trachea to the large bronchi and that some narrowing is potentiated by anticholinesterase inhibitors and prevented by atropine [483,484]. Further work has shown that histamine and other mediators, chemical or mechanical irritation, and dust all produce bronchoconstriction, and that in some cases this may be experimentally abolished or diminished by vagotomy or anticholinergics [485–491]. There is therefore a reflex autonomic pathway by which irritant bronchial stimuli result in the passage of afferent signals to the vagal nuclei in the brainstem, from which efferent signals return to the lungs via the vagus nerve, causing release of acetylcholine at the neuromuscular junction. It is at this point that anticholinergic bronchodilators act by opposing vagally mediated bronchoconstriction. Improved understanding of the pharmacology of muscarinic receptors has led to the identification of three types in the lung. Blockade of two of these types, known as M<sub>1</sub> and M<sub>2</sub> receptors, opposes acetylcholine-mediated bronchoconstriction, whereas blockade of M<sub>3</sub> receptors may be counterproductive by

increasing acetylcholine release. The knowledge that both ipratropium and oxitropium are unselective muscarinic receptor antagonists has stimulated a search for more selective drugs in the hope that these will prove more effective bronchodilators. One such investigational drug is triatropium bromide, which has a prolonged action on M<sub>1</sub> and M<sub>2</sub> receptors and offers the promise of once-daily dosing [492].

Studies in normal subjects have implied that some normal bronchial tone is provided by the release of acetylcholine from vagal motor nerve endings and that atropine can variably inhibit reflex bronchoconstriction produced by irritants such as sulphur dioxide [493]. Anticholinergic drugs have also been shown to provide some protection from the effects on the airways of the muscarinic agonist methacholine, in both normal subjects and asthmatics [494]. Reports of their protective effect in bronchoconstriction caused by exercise and cold air are conflicting, some subjects being protected and others not [495,496]. Similarly reports of their protective effect in antigen challenge are contradictory, and  $\beta_2$  agonists have been found to be more effective [497].

Inhalation of anticholinergic agents produces a slower onset of bronchodilatation than that seen following  $\beta_2$  agonists, the maximum bronchodilator effect occurring between 60 and 120 min [498]. Half this response is achieved within 3 min and 80% of it by 30 min [499]; after peaking, the duration of action wanes gradually over the space of 6 h, lasting somewhat longer than most  $\beta_2$  agonists [499]. The rate of onset of action of oxitropium is similar to that of ipratropium. It has been claimed to have a longer duration of action, enabling twice-daily dosing, but this could reflect the relatively higher dose of oxitropium delivered by a single actuation of the MDI (100  $\mu$ g oxitropium vs. 20–40  $\mu$ g ipratropium). One study that compared the use of the two compounds in asthma found no difference in duration of bronchodilator effect [500].

#### *Administration, absorption and metabolism*

Ipratropium bromide is available for administration only by inhalation, either by pressurized and dry-powder MDIs or in the form of a 0.025% solution for use with a jet nebulizer. Oxitropium is available for administration only by pressurized MDI. Unlike their parent compound atropine, they are relatively lipid insoluble. This property has largely overcome the adverse effects encountered as a result of the absorption of inhaled atropine sulphate when this substance was used as a bronchodilator [501]; furthermore, unlike atropine, ipratropium and oxitropium do not cross the blood–brain barrier and produce no central effects [502]. The minute amounts absorbed from the respiratory and gastrointestinal tracts are metabolized and excreted both in inactive form and as the parent compound in the urine.

### *Dosage*

Ipratropium bromide is an effective bronchodilator when given by MDI (pressurized or dry powder) at a standard dose of 40 µg three to four times daily. As the drug is well tolerated, its effect may sometimes be augmented by doubling the dose. This may be achieved by using a proprietary inhaler that delivers 80 µg per two inhalations. The drug is also available as a 0.025% solution for administration of up to 500 µg (2 mL) 6-hourly by nebulizer. The dose of oxitropium bromide is 200 µg three or four times daily by pressurized MDI.

### *Adverse effects*

The effects of belladonna poisoning have long been recognized [503], systemic absorption of atropine producing tachycardia, blurring of vision, urinary retention, drying of mucous secretions and central effects including mental confusion. Fortunately the lipid solubility of ipratropium prevents significant absorption and avoids most of these problems. However, an unpleasant taste and dryness of the mouth are sometimes noticed with this drug. There has been concern that ipratropium might cause drying of the respiratory secretions, resulting in impaired mucociliary clearance, but work using radioactively labelled inhaled particles in patients with airflow obstruction has failed to show that this occurs even at high inhaled doses of ipratropium [504]. Occasional paradoxical bronchoconstriction has occurred [505]; this was probably the result of the hypotonicity of the original nebulizer solution, a physical property that has now been corrected [506]. Others have suggested that the bromide radical contained in the molecule (Fig. 9.21) may cause an idiosyncratic hypersensitivity reaction in some patients [507], although this has not been confirmed. Later work showed that preservatives such as benzalkonium chloride and EDTA present in earlier formulations of ipratropium bromide solution could cause bronchoconstriction [508]. These have now been removed by the manufacturers. The acidity of the nebulizer solution has been suggested as a possible cause of bronchoconstriction in infants [509].

Just as respiratory physicians see patients who wheeze as a result of the topical ocular application of  $\beta$ -blocking drugs such as timolol prescribed by ophthalmologists for glaucoma, so our colleagues in the eye clinic occasionally see patients with the ocular emergency of acute angle closure glaucoma caused by nebulized ipratropium [510]. The problem arises because nebulized ipratropium escapes around the edge of a face mask and comes into contact with the eyes [511]. This relaxes the smooth muscle of the iris, dilating the pupil and causing the iris to come into contact with the lens. This blocks the flow of aqueous humour from its site of production in the ciliary body through the pupil into the anterior chamber, so that pres-

sure builds up in the posterior chamber [512]. Patients may complain of misty vision and headache, and sometimes coloured haloes (caused by corneal oedema) may be seen around bright lights. These patients may be found to have a red eye and semi-dilated fixed or sluggish pupil. The cornea may appear cloudy. One or both eyes may be affected. Treatment is by lowering the intraocular pressure medically and an urgent referral to an ophthalmologist is made. Failure to treat may result in permanent visual loss or blindness. Predisposed individuals are hypermetropic (long-sighted) with a shallow anterior chamber and may be identified by holding their convex distance lenses close to small print, which will be magnified [513]. The problem may be avoided by using a mouthpiece rather than a mask for nebulization or, if this is impracticable, by taping the top of the mask to the face at the level of the eyes.

### *Principal uses in respiratory medicine*

Anticholinergic drugs only act on the vagally mediated component of reflex bronchoconstriction, whereas  $\beta$  agonists relax smooth muscle irrespective of the nature of the constrictor stimulus and are more effective as bronchodilators in asthma, in which condition a variety of non-neurally mediated bronchial challenges might act as triggers. Despite these considerations, ipratropium bromide has been shown to have a significant bronchodilator effect in patients with asthma in the acute and non-acute setting [514–516], and also in patients with COPD with some potential for reversibility of airflow limitation [499,517], which in this group may partly result from increased vagal tone. The maximal bronchodilator effect of anticholinergic agents is achieved more slowly than that seen with  $\beta_2$  agonists [498], and the peak bronchodilator effect achieved with  $\beta_2$  agonists is probably somewhat greater in asthma than is the case with ipratropium [518]. For these various reasons, ipratropium bromide is not a first-choice bronchodilator in the treatment of asthma. The value of ipratropium in the prophylaxis of exercise-induced asthma is also limited [495,519] and it is common experience that  $\beta_2$  agonists are more effective. Differences in airway responsiveness between ipratropium and  $\beta_2$  agonists are likely to be small and of doubtful clinical significance in COPD [520], a clinical state in which 'reversibility' itself is likely to be small as a result of the underlying pathological processes. There is nevertheless retrospective evidence to suggest that extended treatment with an inhaled anticholinergic agent produces improved lung function in patients with COPD [521].

The combination of a  $\beta_2$  agonist with an anticholinergic drug is pharmacologically enticing, as an additive effect might be expected. A number of studies, over both the short and longer term, have claimed to show benefit from

combination therapy in both asthma and COPD. Again, such improvements are usually small so that some workers report no benefit whereas others report 'trends' that fail to reach statistical significance [522]. This suggests that in most patients any improvement in either ventilatory capacity or duration of action resulting from combination therapy is likely to be of dubious clinical significance and that anticholinergic agents such as ipratropium are not first-line agents in conditions presenting with airflow limitation [495,522,523]. However, there are data which suggest that nebulized ipratropium and salbutamol given together sometimes produce a better response than either drug alone in severe asthma [524]. In the same clinical situation, it has also been claimed that sequential nebulized ipratropium given 2 h after nebulized salbutamol produces a greater effect than simply repeating the same dose of salbutamol [525]. A comparison of nebulized salbutamol and ipratropium with salbutamol alone found no benefit from the combination in hospitalized patients treated for acute exacerbations of COPD [526], so that a better practice might be to give the  $\beta_2$  agonist first and to add ipratropium later if the patient is not progressing satisfactorily. Whatever the evidence, it has been common hospital practice in severely breathless patients admitted with either acute severe asthma or COPD to give a combination of nebulized  $\beta_2$  agonist and ipratropium, and hard-pressed house staff may find the 2-hourly check for sequential treatment theoretically attractive but often practically unachievable.

There also seems, on present evidence, to be no good reason for using a combination dose of a  $\beta_2$  agonist and ipratropium in a single proprietary MDI as a first choice in the treatment of asthma or COPD; these inhalers currently provide 90–100  $\mu\text{g}$ /puff salbutamol and 18–20  $\mu\text{g}$ /puff ipratropium (USA and UK) or 100  $\mu\text{g}$ /puff fenoterol and 40  $\mu\text{g}$ /puff ipratropium as marketed in the UK [527]. A double-blind trial comparing the effect of a metered-dose combination of salbutamol 100  $\mu\text{g}$ /puff and ipratropium 20  $\mu\text{g}$ /puff with either drug alone in a large group of patients with moderately severe COPD found significantly greater improvements in  $\text{FEV}_1$  in patients receiving the combination, although in absolute volumetric terms the improvements were small and there were no significant improvements in peak expiratory flow or symptom scores [528].

The discrepancies in the responsiveness of patients with asthma or COPD to ipratropium may be explained by individual differences in the contribution of the parasympathetic nervous system to bronchoconstriction. Thus in some patients neural reflexes may be potent, and it is possible that chronic bronchial inflammation or respiratory epithelial damage may provoke a bronchial smooth muscle response by neural pathways rather than by the local release of cellular mediators [529]. Clearly, parasympathetic neural responses only represent one of many

Fig. 9.22 Structure of (a) theophylline and (b) caffeine.

different pathways of bronchial airway responsiveness [484,530].

Ipratropium may be effective for watery rhinorrhoea when used as a topical nasal spray at a dose of 42  $\mu\text{g}$  (two sprays) to each nostril two to four times daily [531].

### Theophylline and related compounds

Theophylline is a naturally occurring member of a group of compounds known as methylxanthines and is the oldest asthma medication still in routine use. It is found in the leaves of the tea plant and is closely allied chemically to caffeine, another methylxanthine also found in tea, coffee and chocolate (Fig. 9.22). Strong coffee was recognized as an asthma remedy in the nineteenth century and theophylline continues to be widely prescribed for the relief of wheeze. The use of theophylline waned with the discovery of a seemingly safe and effective method of bronchodilatation in the form of inhaled  $\beta_2$  agonists and because of the side-effects encountered with earlier more rapid release xanthine preparations. However, there was a revival of interest in this drug following the introduction of various sustained-release preparations, which have been increasingly used particularly when  $\beta_2$  agonists or other treatment has produced an inadequate response [532]. Aminophylline is a salt of theophylline that has been made more soluble than the parent compound at neutral pH by the addition of an otherwise therapeutically useless ethylenediamine radical, and for many years has had an 'add on' parenteral role in patients with severe airflow limitation. Choline theophyllinate is a further salt of theophylline that has no particular advantage over the parent compound.

#### Mode of action

The clinical effects of theophylline appear to result from the inhibition of phosphodiesterases, the antagonism of adenosine receptors and other molecular mechanisms that are as yet ill understood [533,534]. Methylxanthines have been known for years to inhibit cyclic nucleotide phosphodiesterase (PDE), thereby retarding the hydrolysis and breakdown of cyclic AMP and cyclic GMP. The increased intracellular concentrations of cyclic AMP (cf. mode of action of sympathomimetic bronchodilators) and cyclic

GMP that result are associated with smooth muscle relaxation in the bronchial walls and it was thought that this mechanism was sufficient explanation for the action of theophylline [535]. One problem with this explanation for the effects of theophylline is the experimental evidence suggesting that for PDE inhibition to occur, much higher levels of theophylline would need to be attained than are clinically possible [536]. It is now recognized that PDE comprises several families of isoenzymes that not only act on airway smooth muscle but also have effects on those inflammatory cells implicated in the processes by which airways become hyperactive in diseases such as asthma [537]. Theophylline is an unselective PDE inhibitor and the knowledge that certain PDE isoenzymes, such as types 3 and 4, are more potent than others at relaxing airway smooth muscle [538] has led to the search for specific PDE isoenzyme inhibitors [539], a quest that has not so far borne clinical fruit. PDEs are also present in inflammatory cells and PDE-4 is the predominant isoenzyme in this regard, being found in eosinophils, neutrophils, monocytes, alveolar macrophages and T lymphocytes [537,540]. This knowledge has given added impetus to pharmaceutical efforts to exploit any anti-inflammatory and immunomodulatory effects of specific PDE-4 inhibitors that might prove to be clinically significant [492]. Another mechanism of action other than PDE inhibition is the antagonism of adenosine receptors [541]. This may not cause bronchodilatation *per se* but could have some clinical effects by reducing diaphragmatic muscle fatigue, as well as acting centrally to increase ventilation during hypoxia and also reducing mediator release from mast cells [534,542–545]. Other effects of doubtful significance include prostaglandin and other mediator inhibition [542,546], and the alteration of intracellular calcium ion concentrations [542,547].

*Administration, metabolism and excretion*

Xanthines are usually administered orally in one of three chemical formulations: theophylline, aminophylline (theophylline and ethylenediamine) and choline theophyllinate. In addition to the ‘plain’ preparations, there are currently six different proprietary modified-release formulations listed in the *British National Formulary* [58]. These have been designed to maintain therapeutic plasma levels for up to 12 h, so that not more than two doses are required daily.

Absorption of ‘plain’ preparations from the gut is rapid and complete, the peak plasma level being achieved in about 1.5 h. The plasma half-life is very variable between subjects but is about 6–8 h on average, so that at least three doses daily are usually needed for a continuous effect. Modified-release preparations tend to achieve a peak plasma level about 4–6 h after a morning dose. Absorption may be slower during the night so that the peak level may

be achieved 8 h after a bedtime dose. The half-life is also variable but allows twice-daily dosage, a relatively steady state being achieved after 3 days on a given dose. Once-daily dosing does not provide adequate plasma concentrations for 24 h, levels tending to fall outside the therapeutic range by about 14 h, so that this approach is best adopted when treating nocturnal symptoms [548]. Ordinary (short-acting) formulations peak at about 2 h and elixirs after about 15 min. About half the drug is protein-bound and the average volume of distribution is 0.5 L/kg, an observation used when calculating the dose from plasma levels (see below).

Xanthines undergo metabolism by the P450 microsomal enzyme system in the liver, with quite wide variations in rate between individuals. Less than 20% of the oral drug is excreted in the urine unchanged, the remainder being accounted for by relatively inactive metabolites [549]. The plasma half-life of all the xanthine bronchodilators can be affected by the various factors listed in Table 9.10. For example, tobacco (or cannabis) produces a shorter theophylline half-life as a result of microsomal liver enzyme induction and thus theophylline clearance may remain enhanced for over 3 months after tobacco abstinence [550,551]. Clearance is also enhanced by liver enzyme-inducing drugs such as rifampicin, phenobarbital (the level of which may itself be lowered by theophylline) and other anticonvulsants. On the other hand, clearance is reduced and the half-life prolonged with increasing age, with liver disease including congestion or hypoxia due to heart failure, in febrile illness, if the diet is low in carbohydrate and high in protein, and if the patient takes various drugs, including cimetidine, macrolides, ciprofloxacin, isoniazid, fluconazole, calcium-channel blockers and the antidepressants fluvoxamine and viloxazine (see Table 9.10), in which situations toxicity is more likely to be

**Table 9.10** Factors affecting theophylline elimination (see text).

Decreased elimination (theophylline level increased)	Increased elimination (theophylline level decreased)
Erythromycin and other macrolides	Tobacco or cannabis smoking
Ciprofloxacin*	Rifampicin
Cimetidine	Phenobarbital
Norfloxacin	(phenobarbitone)
Fluvoxamine*	and primidone
Combined oral contraceptives	Carbamazepine
Diltiazem/verapamil	Phenytoin
Allopurinol (high dose)	Youth
Old age	
Cardiac failure	
Liver disease	
Hypoxaemia	
Viral infection	
Fever	

\* Halve dose of theophylline.

encountered [552–555]. Potentiation of xanthines is particularly strong with ciprofloxacin and fluvoxamine, so that the Committee on Safety of Medicines recommends that if xanthines are used together with either of these then the dose of xanthine should be halved. A 75% reduction in the dose is recommended if theophylline is used in the presence of hepatic cirrhosis. The drug crosses the placenta but there is no evidence of teratogenicity. It also appears in breast milk.

Aminophylline may be given intravenously in the management of severe asthma but safer alternatives such as nebulized  $\beta_2$  agonists should be used first, and parenteral aminophylline omitted if the patient usually takes an oral theophylline preparation, at least until plasma levels are known, so that dangerous toxicity may be avoided. The care with which this situation should be handled highlights the principal drawback of the theophyllines, i.e. their narrow therapeutic index, the margin between a satisfactory therapeutic result and the development of toxic side-effects often being uncomfortably small. This problem can only be adequately addressed by making use of plasma theophylline assays and this is discussed in the following sections.

The pharmacokinetics of parenteral theophylline are apparently unaffected by oral corticosteroid therapy [556].

#### *Oral dosing and plasma theophylline levels*

Sustained (modified)-release preparations are preferred if an oral xanthine drug is used. The modified-release preparations [58] are all similar in their effects but individual brands are not interchangeable dose for dose because of their different theophylline release mechanisms. Many patients are put on one or two such tablets once or twice daily and left to take them indefinitely, often with no objective assessment of effect on the part of the physician and without any clear subjective improvement on the part of the patient, many of whom are undertreated. As well as theophylline having a narrow therapeutic index, there are also wide intersubject variations in the rate at which it is metabolized, so that if these drugs are to be useful then the maximum bronchodilator effect has to be sought by measuring plasma levels and manipulating the dosage within the usual therapeutic range of 10–20 mg/L. Chemistry laboratories in the UK have long been wedded to SI rather than mass units, even for reporting drug levels, despite the merciful fact that drugs are still prescribed in mass units. Conversion from mass units to SI is obtained by multiplying by 5.5, giving a therapeutic range of 55–110  $\mu\text{mol/L}$ ; the opposite conversion is achieved by multiplying by 0.18. The American Thoracic Society, recognizing that significant benefits may occur within a lower dose range, has recommended that clinicians should initially aim for plasma concentrations of 5–15 mg/L (27.5–82.5  $\mu\text{mol/L}$ ) [557]. The therapeutic range for theophyllines is intended

for guidance only, as useful bronchodilatation may occur below this range in some patients and will continue without side-effects if the upper figure is exceeded in others. However, it is clear that dosages may be safely increased at concentrations below 10 mg/L (55  $\mu\text{mol/L}$ ) and that serious toxicity is much more likely if blood levels are allowed to exceed 20 mg/L (110  $\mu\text{mol/L}$ ) and that fatal accidents may occur at 25 mg/L (137.5  $\mu\text{mol/L}$ ) or more [532,558]. Toxicity becomes unusual at levels below 15 mg/L (82.5  $\mu\text{mol/L}$ ), but may occur in about 15–20% of patients within the usual therapeutic range of 10–20 mg/L (55–110  $\mu\text{mol/L}$ ). As patients vary widely in the dose required to keep the plasma level therapeutic [559], a 'recipe book' approach is inappropriate and theophylline levels should be measured. These may be taken 2–3 days after onset of treatment or change in dose. An initial dose of about 10 mg/kg daily is used [560], peak plasma levels being measured 4–6 h after the morning dose of a sustained-release product, so that the drug may be swallowed in the morning and the sample taken in the afternoon. Trough levels may be obtained immediately before the next dose is due but are in practice seldom measured. When the trough level is low with a long-acting preparation, attempts should not be made to increase the level by upward adjustment of the dose before ensuring that the peak level is not approaching the upper limit of the therapeutic range, otherwise peak level toxicity may be produced [561]. A linear relationship has been obtained between the logarithm of the plasma theophylline concentration within the range 3–20 mg/L (16.5–110  $\mu\text{mol/L}$ ) and  $\text{FEV}_1$  [562], so that incremental increases in concentration of the drug at levels below 10 mg/L (55  $\mu\text{mol/L}$ ) produce only small changes in  $\text{FEV}_1$ , whereas above this level more substantial increases in  $\text{FEV}_1$  are produced.

It is of some importance that patients who are already stabilized on one brand of modified-release theophylline or aminophylline should stay on the same brand as there are variations in bioequivalence between different makes, and thus the brand name rather than the generic name should therefore be stated on prescriptions.

#### *Intravenous dosing and plasma theophylline concentrations*

Patients who are ill enough to require admission to hospital with asthma or COPD and who do not respond to nebulized bronchodilators and other measures are frequently considered for treatment with intravenous aminophylline by infusion. Before commencing such an infusion, a loading dose may be given over the space of 30 min in order to achieve a therapeutic level without undue delay, while at the same time exercising sufficient caution to avoid the untoward effects that may follow a more rapid injection. It should first be established that the patient was not taking xanthines, including certain 'over the counter' proprietary preparations, prior to admission. If there is

doubt about this, an urgent level should be requested. In order to make the calculations, the volume of drug distribution ( $\text{Vol}_D$ ) is assumed to be 0.5 L/kg (i.e. half the patient's body weight in kg =  $\text{Vol}_D$  in litres) and the loading dose ( $\text{Dose}_L$ ) can be calculated according to the equation:

$$\text{Dose}_L = \text{Conc}_{PD} \times \text{Vol}_D \quad [9.3]$$

where  $\text{Conc}_{PD}$  is the desired plasma theophylline concentration (mg/L). As  $\text{Vol}_D$  may vary according to the state of hydration and other factors, it is suggested that the lower end of the therapeutic theophylline range is aimed for, i.e. 10 mg/L (55  $\mu\text{mol/L}$ ). Thus for a 60-kg patient on no xanthine treatment within the last 24 h:

$$\text{Dose}_L (\text{mg}) = 10 \times 30 = 300 \text{ mg aminophylline}$$

In the case of patients who have already been taking oral theophylline or in whom there is any suspicion that they might have done so, the plasma theophylline level must be obtained before any loading dose is given, otherwise the chance of serious toxicity is increased [563]. Once the plasma theophylline level is available, the reduced loading dose can be calculated according to a modification of Eqn 9.3 as follows:

$$\text{Dose}_{LM} = (\text{Conc}_{PD} - \text{Conc}_{PM}) \times \text{Vol}_D \quad [9.4]$$

where  $\text{Dose}_{LM}$  is the modified loading dose (mg) and  $\text{Conc}_{PM}$  is the measured plasma theophylline concentration (mg/L) before the modified loading dose. Once again, as  $\text{Vol}_D$  may vary according to the patient's state of hydration and other factors, it is suggested that the lower end of the therapeutic theophylline range is aimed for, i.e. 10 mg/L (55  $\mu\text{mol/L}$ ). Thus for a 60-kg patient in whom  $\text{Conc}_{PM}$  is found to be 5 mg/L (27.5  $\mu\text{mol/L}$ ):

$$\text{Dose}_{LM} = (10 - 5) \times 30 = 150 \text{ mg aminophylline}$$

This dose may be infused over 30 min before commencing the maintenance infusion. A further theophylline estimation may be carried out 15 min after completing the loading dose to determine the peak level. In practice, although more rapid analytical techniques are being developed [564], by the time the pre-dose plasma theophylline measurement has been obtained from the laboratory, many patients will have responded to a nebulized  $\beta_2$  agonist or a parenteral  $\beta_2$  agonist (subcutaneous or intra-

venous terbutaline or salbutamol) and the aminophylline infusion may prove unnecessary. Assuming that this is not the case and that the post-loading dose level is therapeutic, then a maintenance infusion may be commenced at a rate of 0.5 mg/kg/h. This dose may need adjustment upwards to about 0.9 mg/kg/h in children or young adult smokers, or reduction by about half in patients with right heart failure or liver disease [558,565,566]. Plasma theophylline levels may be checked 4–6 h into the infusion or at any time if toxicity is suspected.

Rectal administration of aminophylline in suppository form, although used in the past to improve nocturnal wheeze, produced inadequate blood levels [567], sometimes causing irritant proctitis, and has been superseded by the administration of a modified-release oral preparation at night-time, if indeed a xanthine preparation rather than a long-acting  $\beta_2$  agonist is chosen for this purpose.

In general, oral theophyllines are as effective bronchodilators as oral  $\beta_2$  agonists but carry the same disadvantage that their therapeutic effect is, unlike inhaled bronchodilators, directly related to their plasma level so that adverse effects are more liable to occur.

#### Adverse effects

Theophylline has a narrow therapeutic index, i.e. significant adverse effects (Table 9.11) may occur at plasma concentrations close to those needed to produce bronchodilatation. The most common side-effects of xanthines are nausea, insomnia, nervousness and headache (as might be experienced after taking too much tea or coffee). Such symptoms are more likely to occur if the plasma theophylline concentration increases rapidly above 10 mg/L (55  $\mu\text{mol/L}$ ) and may be avoided if care is taken to increase the dose gradually [568]. Other gastrointestinal symptoms include anorexia, vomiting and diarrhoea. About 5% of patients may experience unacceptable gastrointestinal symptoms at plasma concentrations below 14 mg/L (77  $\mu\text{mol/L}$ ) [569]. These symptoms usually abate quickly if a dose is omitted and subsequent downward adjustment made. The most serious adverse effects are major seizures and ventricular tachydysrhythmias. These are rare at levels below 55 mg/L (110  $\mu\text{mol/L}$ ), tending to occur with blood levels exceeding 30 mg/L

**Table 9.11** Adverse effects of theophylline.

Gastrointestinal	Neurological	Cardiovascular	Allergic
Nausea	Headache	Cardiac dysrhythmias	Rashes
Anorexia	Tremor	Flushing	Pruritis
Vomiting	Irritability		Fever
Abdominal pain	Insomnia		
Diarrhoea	Confusion		
	Dizziness		
	Tinnitus		
	Major seizures		

(165  $\mu\text{mol/L}$ ). Such levels may be the result of gradual overdosage from an infusion, slow-release oral product or an inappropriately rapid intravenous bolus injection. Clearly, in an already hypoxic patient struggling to breathe as a result of severe bronchoconstriction, a grand mal seizure may deliver the *coup de grâce* and should be avoided at all costs. Rarely, an allergic reaction to the ethylenediamine component of aminophylline may occur, with an erythematous or urticarial rash; occasionally exfoliative dermatitis has been reported [570].

As with any oral medication, deliberate overdosage may occur [571,572]. When recent oral overdosage has occurred and the patient is conscious, gastric lavage or emetics may be used and can be followed by repeated oral doses of activated charcoal [573]. If this proves impracticable, charcoal haemoperfusion may need to be considered [574]. Serious overdosage can produce ventricular tachydysrhythmias and convulsions and may result in fatality [532,575,576].

#### *Principal uses in respiratory medicine*

Theophyllines are widely used in the management of asthma (see Chapter 35) and COPD (see Chapter 23). In the UK, their usual application in asthma is as supportive oral treatment in more chronic asthmatics whose symptoms are inadequately controlled with a  $\beta_2$  agonist and inhaled steroid alone [577] and also in patients with nocturnal wheeze [578], modified-release preparations being used in both cases. A recent study of patients with moderate asthma who had persistent symptoms showed that the addition of theophylline to low-dose inhaled glucocorticosteroid produced similar benefits to changing to high-dose inhaled steroid [579].

Intravenous aminophylline may be effective in acute severe asthma or exacerbations of chronic obstructive lung disease in those patients who remain profoundly ill despite treatment with nebulized or parenteral  $\beta$  agonists. However, it should be used with caution, as outlined above, because of the risks of serious toxicity [580].

The place of oral theophylline in COPD is more controversial, some studies having found improved effort tolerance, others not [581–584].

### **Non-steroidal prophylactic drugs for use in asthma**

#### *Sodium cromoglicate*

Sodium cromoglicate (sodium cromoglycate, cromolyn sodium) is a synthetic bis-cromone with a distinctively symmetrical molecular structure (Fig. 9.23). It was synthesized in the UK in 1965 following the observation that a related botanical substance, khellin, contained in folk medicines had asthma-relieving properties [585]. Sodium

Fig. 9.23 Structure of sodium cromoglicate.

cromoglicate has no direct bronchodilator properties but has nevertheless proved very useful in certain aspects of prophylactic asthma management.

#### *Mode of action*

The mode of action of sodium cromoglicate is incompletely understood. It is known to have a stabilizing effect on mast cell membranes so that the release of various chemical mediators of asthma within the airway wall is inhibited [586]. As a result of the practical observation that sodium cromoglicate was particularly effective in asthma in which extrinsic allergic factors were clinically obvious, it was thought that mast cell stabilization might be due to a direct blocking action on early-phase IgE antibody-antigen reactions. However, it has subsequently become clear that sodium cromoglicate can also prevent or reduce non-allergic bronchoconstriction, such as that following exercise [587,588], exposure to cold air [589] or chemical irritants such as sulphur dioxide [590]. It has been suggested that mast cell stabilization may be brought about by the phosphorylation of a high molecular weight protein that results in the blocking of ionic calcium transport across the cell membrane [591]. The view that mast cell stabilization cannot account for all the actions of sodium cromoglicate is supported by the observation that other more potent mast cell stabilizing substances may be clinically ineffective in asthma [592]. There is some experimental evidence to suggest that sodium cromoglicate may exert a possible neural effect, suppressing the activity of sensory nerve endings in the lungs [593]. Studies carried out on the bronchial secretions and blood of asthmatics treated with sodium cromoglicate have shown that this form of therapy may be associated with a reduction in eosinophil counts in the blood, sputum and bronchoalveolar lavage fluid, as well as a reduction in allergen-specific plasma IgE. It is also evident that, in addition to its early-phase mast cell stabilizing effect, sodium cromoglicate also reduces those late-phase asthmatic responses mediated by other inflammatory cells such as neutrophils, eosinophils and monocytes [594].

#### *Administration and excretion*

Sodium cromoglicate was originally made available as a

dry micronized powder contained in capsules and administered using a pocket-sized tubular device into which the powder was released automatically and from which it was sucked by the patient through a small turbine. This method of administration is still useful in children who are not old enough to master the pressurized MDI. A 1% aqueous solution of sodium cromoglicate is available for nebulization and has a limited application for patients (usually small children) who are too young to use either of the other devices.

As with all medications administered by inhalation, most of the dose becomes impacted in the mouth and throat and is subsequently swallowed, being excreted unchanged in the faeces. Approximately 1–2 mg of the standard 20 mg inhaled powder dose reaches the lungs [595]. This is absorbed into the blood and excreted unchanged, about half in the urine and the remainder in bile [588]. The plasma half-life is about 80 min. It does not cross the placenta or blood–brain barrier. A sodium cromoglicate nasal spray is available for the treatment of allergic rhinitis, as are ophthalmic drops for conjunctivitis.

#### *Dosage and modes of use*

The standard inhaled dry powder dose is one 20 mg capsule four times daily initially. In addition to the active drug, each capsule also contains 20 mg of lactose carrier. Two inhalations (2 mg) four times daily from the MDI is considered a clinically equipotent dose, although the manufacturers have substituted a higher-strength MDI in Europe that delivers 5 mg per actuation. A solution containing 20 mg sodium cromoglicate in 2 mL of water is also available and has to be taken using a nebulizer.

Ideally, when sodium cromoglicate therapy is commenced the preparation should be taken regularly four times daily, with peak flow charting to assess the response. The treatment should not be abandoned unless there has been no improvement at 3–4 weeks despite good patient compliance. If a good response is achieved, then small decremental dose reductions may be possible but patients, or their parents, need to be discouraged from being over-hasty about this and it is common, when a clear response has been achieved, for a twice, three or four times daily dose to be continued for months or years. The most encouraging results occur in children with obviously allergic asthma, although good results may be obtained in some adults. Response is difficult to predict [596] and if objective improvement is not achieved then sodium cromoglicate should be discontinued. Patients need to be told that an improvement may take a good 2 weeks to become evident.

Patients whose symptoms occur seasonally should start regular sodium cromoglicate a few weeks before the anticipated onset of wheeze and should continue regularly until the end of their 'season'.

In addition to regular prophylactic use, sodium cromoglicate can also be taken to forestall exercise-induced asthma, 20 mg of powder or a 10-mg metered-dose inhalation being taken about 30 min before the anticipated exertion. Occasionally a higher dose of sodium cromoglicate is required to prevent exercise-induced asthma, using the MDI that delivers 5 mg per actuation. Sodium cromoglicate is commonly 'added on' to a separately inhaled  $\beta_2$  agonist if control of exercise-induced asthma with the latter alone is poor.

There is no good pharmacological indication for taking sodium cromoglicate and a  $\beta$  agonist in combined dry powder form. However, some clinicians have prescribed such formulations as a ruse to get preventive medication into the lungs of patients who would be unlikely to comply with prophylactic treatment but who can be depended upon to 'dose up' with bronchodilator.

#### *Adverse effects*

Sodium cromoglicate must be one of the safest medications available for prescription and this is an important reason for its attraction in paediatric practice. Side-effects have been reported in about 2% of patients. These are mild and may take the form of pharyngeal irritation, occasionally the dry powder form producing cough and wheeze, in which case a  $\beta_2$  agonist may be taken first or the patient switched to the pressurized MDI. Skin rashes may rarely occur [597].

The place of sodium cromoglicate in the wider scheme of asthma management is discussed in Chapter 35.

#### *Nedocromil sodium*

Nedocromil sodium is the disodium salt of a paraquino-line tricyclic dicarboxylic acid (Fig. 9.24). Although chemically unrelated, it has a somewhat similar profile of action to sodium cromoglicate, also affecting both the early and late responses in asthma.

#### *Mode of action*

The mode of action of nedocromil is not fully understood. Like sodium cromoglicate, it has been shown to stabilize mast cells and to inhibit *in vitro* mediator release and activation of other inflammatory cells [598,599]. It has been

Fig. 9.24 Structure of nedocromil sodium.

shown to inhibit antigen-induced inflammatory mediator release from bronchoalveolar lavage cells in experimental animals [600]. As with sodium cromoglicate, it has also been found to inhibit the bronchoconstrictor response to various immunological and non-immunological stimuli in humans [598,599]. It may protect against exercise-induced asthma and against bronchoconstriction induced by both antigen challenge and other non-specific stimuli including sulphur dioxide [599,601–604]. It has been speculated that, like sodium cromoglicate, nedocromil may also have an effect on sensory nerve ending in the lungs [604]. Improvement in the control of bronchial asthma in humans was achieved when it was administered four times daily for 1 month [605]. In one study, 2–16 weeks of treatment with nedocromil 16mg daily appeared to have a similar inhibitory effect on methacholine challenge to that provided by 400µg daily of beclometasone (beclomethasone) dipropionate [606].

#### *Administration, excretion and dosage*

Nedocromil is administered by MDI. It is absorbed from the lung and undergoes no metabolism, being rapidly excreted unchanged in both the bile and urine. The present recommended dose is two inhalations (4mg) four times daily at first, decreasing to two inhalations twice daily if symptomatic control permits. It is licensed for use in both adults and children over the age of 6 years.

#### *Modes of use*

Published work in patients with asthma who were not receiving inhaled steroids has shown that, compared with placebo, nedocromil may improve daytime and nocturnal symptoms and reduce the requirement for existing treatment with  $\beta$  agonists [599,607,608]. Clinical trials comparing nedocromil with sodium cromoglicate in terms of symptom control and lung function have shown nedocromil to have similar or somewhat greater efficacy than sodium cromoglicate [609,610]. On the basis of improvements in peak expiratory flow, 16mg of nedocromil daily has been found to be therapeutically equivalent to 400µg daily of beclometasone dipropionate in some patients [611], albeit at greater economic cost, so that nedocromil may be an alternative for the few patients who are intolerant of low-dose inhaled steroids [599]. However, a low-dose inhaled steroid is likely to be more effective in terms of overall symptom control and also gives the option of upward dose adjustment [607,611]. Claims have been made that the addition of nedocromil enables a reduction in dose of prednisolone in those requiring systemic steroids, although the evidence is conflicting and this effect is unlikely to be strong [599,612,613]. Nedocromil may have an inhaled steroid-sparing effect, in the sense that, compared with placebo, it

produces a better effect on symptoms and peak flow when added to a treatment regimen in which the inhaled steroid dose had been reduced [614]. Increasing the dose of nedocromil beyond 16mg daily does not appear to augment any inhaled corticosteroid-sparing effect [615]. Symptomatic benefit and small improvements in peak flow measurements have been demonstrated by the addition of nedocromil to the regimens of patients with asthma who had troublesome symptoms despite high doses of inhaled steroids [616]. Nedocromil 4mg taken 20min before exercise may attenuate the exercised-induced decline in measured lung function to the same degree as 20mg sodium cromoglicate but its duration of action may be shorter [617].

As with sodium cromoglicate, nedocromil may be regarded as a regular adjunctive therapy in patients with relatively mild persistent asthma whose symptoms are not adequately controlled by  $\beta$  agonists alone. Comparisons of nedocromil with established treatments of known efficacy in clearly defined clinical groups are few in number and have shown no clear-cut clinical advantage of nedocromil over other forms of maintenance therapy. Most clinicians, particularly in adult practice, use an inhaled steroid as initial anti-inflammatory prophylaxis in asthma; nevertheless, sodium cromoglicate or nedocromil may sometimes be used as alternatives for the milder case, particularly those who regard 'steroids' as the devil's own medicine. Patients need to be told that an improvement may take 1–2 weeks to become evident and patient compliance is a problem in medication that may need to be taken four times daily.

Nedocromil is also available as a 1% solution in a metered-dose spray and as a 2% solution for topical use in allergic rhinitis and conjunctivitis respectively.

#### *Adverse effects*

The drug has a rather bitter taste that some patients found unpleasant. This has been quite successfully masked by an added mint flavour. Cough, irritation of the throat and headache are occasional complaints but, as with sodium cromoglicate, the drug appears to be very safe [599,618].

#### *Leukotriene modifiers*

Leukotrienes, like prostaglandins, thromboxane (TX) $A_2$  and prostacyclin, are members of a group of lipid mediators known collectively as eicosanoids. These have inflammatory properties and are liberated from various cells such as mast cells, eosinophils and basophils. The production of eicosanoids is dependent on the arachidonic acid cascade, one branch of which (the cyclooxygenase pathway) produces prostaglandins, TX $A_2$  and prostacyclin, whereas the other (the lipoxygenase pathway) leads to the production and liberation of leukotrienes from

inflammatory leucocytes. A number of eicosanoids, particularly the leukotrienes, are known to play varying roles in the production of inflammation, mucous secretion, reduced mucociliary clearance and tissue injury in asthma. Cysteinyl leukotrienes are known to be extremely potent bronchoconstrictors [619] and much pharmaceutical research effort has recently been centred on this area, with attempts to develop chemicals that either interrupt the synthesis of leukotrienes by interfering with the 5-lipoxygenase pathway or block their action at a common receptor known as the cysteinyl leukotriene type 1 receptor on bronchial smooth muscle. These drugs may be collectively termed 'leukotriene modifiers' or 'antileukotrienes'.

Those orally administered agents that interrupt cysteinyl leukotriene production do so by inhibiting the enzyme 5-lipoxygenase or an associated protein, 5-lipoxygenase-activating protein. Zileuton is an example of a potent 5-lipoxygenase inhibitor, whereas montelukast, zafirlukast and pranlukast are all cysteinyl leukotriene receptor antagonists. These agents only affect one set of inflammatory mediators, and there appears to be much variation in response to these drugs between individual asthmatic subjects. This implies that there is probable patient heterogeneity with regard to the importance of leukotrienes in each individual's asthmatic response and as yet there is no method of identifying those patients in whom leukotrienes may play a more central role.

The limited amount of clinical data currently available gives the impression that these agents will have a relatively weak effect in asthma compared with inhaled steroids or  $\beta_2$  agonists. The effects of these antileukotriene drugs have been initially evaluated against allergen and cold air challenge as well as in exercise-induced and aspirin-sensitive asthma; thus in a group of atopic asthmatics 40 mg zafirlukast taken orally attenuated the early and late responses to allergen challenge in most but not all subjects [620,621]. It also produced a reduction in exercise-induced bronchoconstriction in asthmatics, with quite wide variation between subjects [622]. The addition of zafirlukast to  $\beta$  agonists in a group of patients with mild to moderate asthma was found to be more effective than  $\beta$  agonists alone in a North American randomized, double-blind, multicentre, placebo-controlled trial [623]. The usual intervention in such a group would be to add an inhaled steroid but there is little published work comparing leukotriene-modifying therapy with low-dose inhaled steroids in mild asthma. Some of the data have recently been reviewed [624,625]. It has been suggested that in patients with more severe asthma antileukotriene drugs might enable adequate control of symptoms with a lower dose of inhaled steroid than might otherwise be possible. A more recent controlled trial has shown an inhaled steroid-sparing effect with montelukast in stable asthmatic patients [626]. However, no such steroid-sparing

effect was found in two studies in which the effect of zafirlukast was compared with placebo in patients with asthma taking 400–2000 mg of inhaled steroid daily [627,628]. There is some evidence that leukotriene antagonists may be effective in asthmatics with sensitivity to aspirin and other non-steroidal anti-inflammatory drugs, bronchopulmonary reactions in such patients being associated with hypersecretion of urinary leukotriene (LT) $E_4$  [629,630].

Montelukast is licensed in the UK as an 'add-on' for use in patients with mild to moderate asthma whose symptoms are inadequately controlled by inhaled steroids and inhaled  $\beta$  agonists, and as prophylaxis in exercise-induced asthma [631,632]. It has a 24-h duration of action and is taken as a once-daily dose of 10 mg at bedtime, half this dose being used in children aged 6–14 years. It is rapidly absorbed and extensively metabolized, being excreted by the biliary route. The dose need not be modified in renal insufficiency or in mild to moderate hepatic disease. It should not be taken with food.

Zafirlukast has usually been administered as an oral dose of 20 mg twice daily [633]. It is well absorbed, having a terminal half-life of about 10 h. It is extensively metabolized and mainly excreted in the faeces. It may be used in patients with renal insufficiency but is not advised in those with liver disease. No major adverse effects have been reported. Minor side-effects have included sore throat and headache but these were not significantly more frequent than found with placebo.

Other oral antileukotriene agents currently under investigation include zileuton (available in the USA) and pranlukast [634,635]. These and other leukotriene modifying drugs are still being evaluated and any long-term benefit has yet to be established. On present evidence, they should certainly not be used as 'add-on' therapy in uncritical fashion and may be best introduced in an asthmatic whose control is less than satisfactory but sufficiently stable to enable an objective assessment of the effect of the new drug to be made so that responders may be separated from non-responders, enabling the leukotriene modifier to be continued or discarded as the case may be [636].

## Glucocorticosteroids

Glucocorticosteroid hormones, hereafter referred to simply as 'steroids', are widely used in respiratory medicine, particularly in the treatment of asthma, for which they are still the most effective agents for reducing both airway inflammation and bronchial hyperresponsiveness (see Chapter 35), and in a variety of other pulmonary disorders. All steroids in clinical use are synthetic but are chemically based on the naturally occurring corticosteroids, such as cortisol (hydrocortisone), produced in the adrenal cortex from cholesterol. All steroids, both naturally occurring and synthetic, share the same molecular

configuration of four carbon rings containing 21 carbon atoms. Their clinical and pharmacokinetic properties (potency, distribution, metabolism, duration of action, etc.) depend upon variations on this central structure, so that those compounds with effective anti-inflammatory activity must possess the following:

- 1 a double bond between C-4 and C-5;
- 2 a ketone ( $=O$ ) group in the C-3 position;
- 3 a hydroxyl group (OH) in the C-11 position;
- 4 a two-carbon side-chain in the C-17 position with a ketone ( $=O$ ) group in the C-20 position and a hydroxyl group (OH) in the C-21 position (Fig. 9.25).

Such steroids are known to chemists as 17-hydroxycorticoids. The main endogenously produced steroid is cortisol (hydrocortisone, Fig. 9.26), which is produced by the adrenal cortex. The inactive steroid cortisone, also produced in small quantities by the adrenal, is converted to cortisol in the liver. Similarly, prednisolone, a synthetic analogue of hydrocortisone, is produced in the liver from its synthetic and inactive parent prednisone. Both the beneficial and adverse clinical effects of steroids result from their administration in doses that far exceed the plasma levels achieved by their naturally occurring adrenal glucocorticoid analogues.

### Mode of action

The biological mechanisms by which steroids have their clinical effects remain incompletely understood, despite the fact that they have been in use as therapeutic agents for over 50 years. This relative state of ignorance stems from the considerable complexity of their interactions with

many different biochemical pathways. The summary that follows attempts to concentrate on areas of apparent clinical relevance.

### Gene-modulating effects

Therapeutically administered steroids diffuse passively across cell membranes and selectively bind to glucocorticoid receptors, proteins contained within the cytoplasm of the cells [637,638]. This results in the formation of activated glucocorticoid-receptor complexes, which then migrate across the cell to enter the nucleus where they interact with so-called glucocorticoid-response elements (GREs) in the nuclear chromatin (DNA). Binding of a glucocorticoid-receptor complex with a GRE affects transcription of the mRNA for the specific gene which that GRE regulates, which in turn increases or decreases the output of gene products that modify pre-existing cellular processes [639]. These gene-modulating effects of steroids may have a variety of outcomes. One such outcome is the inhibition or downregulation of a complex network of soluble molecules that act as intercellular messengers (cytokines), thought to be of much importance in the inflammatory response in asthma. Examples of such cytokines are interleukins (ILs), granulocyte-macrophage colony-stimulating factor (GM-CSF), tumour necrosis factor  $\alpha$  (TNF- $\alpha$ ) and interferon  $\gamma$  (IFN- $\gamma$ ). Another outcome is the production of anti-inflammatory proteins, such as lipocortin 1 (or, being a member of the annexin family, annexin 1). Levels of this protein in the respiratory tract have been shown to increase following the administration of exogenous systemic steroids. It is thought that lipocortin 1 has its anti-inflammatory effect by reducing the activity of phospholipase  $A_2$ , an enzyme that plays a key role in a number of inflammatory responses (see below) [640,641]. It is perhaps because such protein synthesis cannot be immediately accomplished that the effects of steroids do not show clinically for 1–3 h after their administration.

### Inhibition of arachidonic acid cascade

One biochemical sequence of events considered important in the development of those changes in the bronchial tree that produce symptoms of asthma is the arachidonic acid cascade. Steroids are believed to be important in inhibiting this chain of events, which is shown in simplified form in Fig. 9.27. The first stage that has been proposed is the disruption of inflammatory-cell membranes, which may result from a variety of immunological, neurological, physical or other forms of insult. This may produce a loss of cell membrane integrity, allowing the influx of calcium ions into the cell. The raised intracellular ionic concentration of calcium may in turn activate the calcium-dependent enzyme phospholipase  $A_2$ . This rate-limiting

Fig. 9.25 Structure of the 21-carbon corticosteroid molecule.

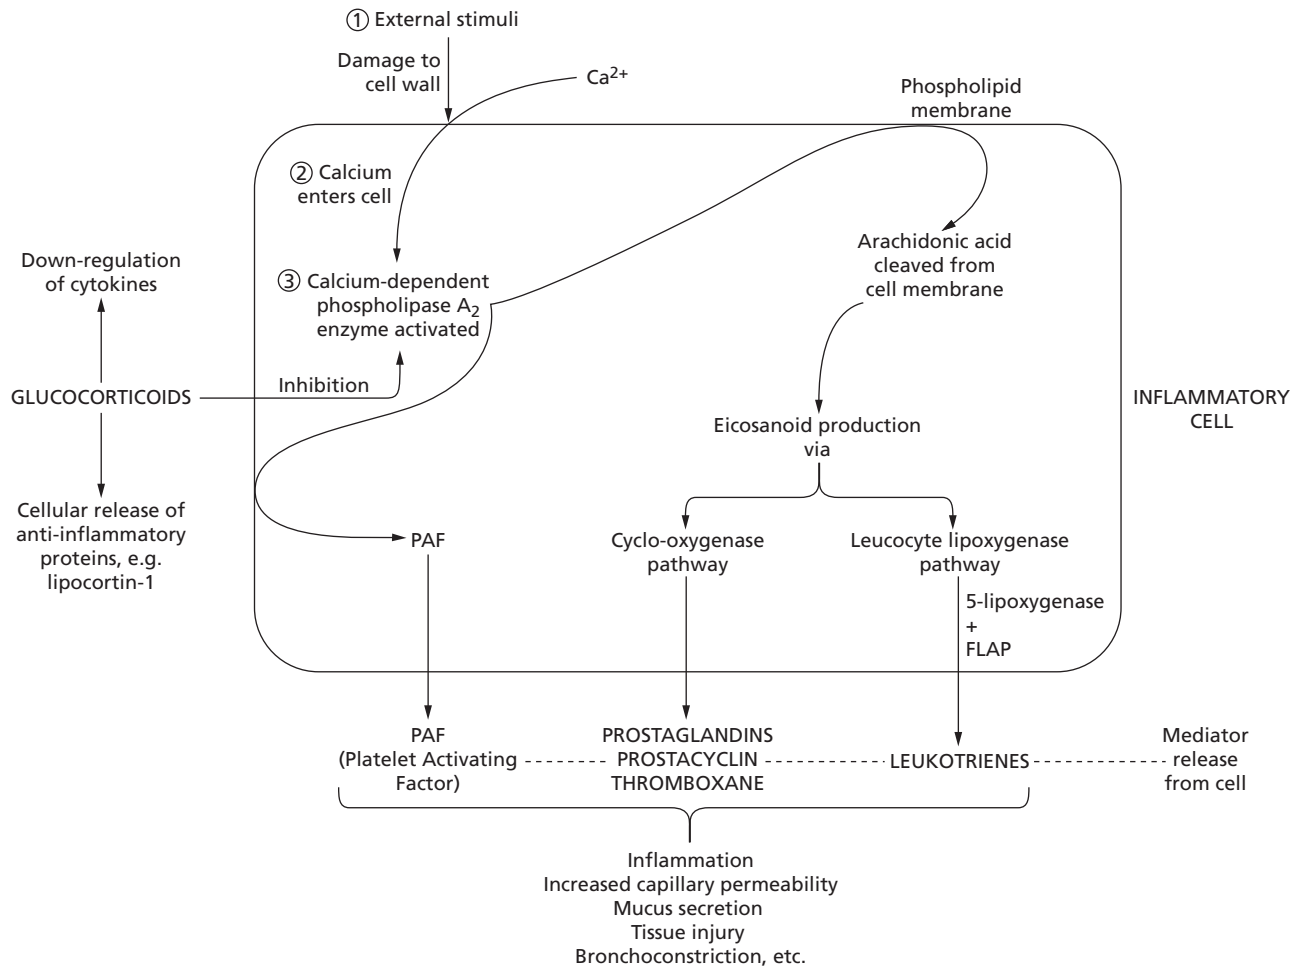

Fig. 9.26 Structure of hydrocortisone (cortisol).

**Fig. 9.27** Inhibition of inflammatory mediator release by corticosteroids.

enzyme cleaves arachidonic acid, a polyunsaturated fatty acid, from the cell membrane phospholipids of which it is a component. Arachidonic acid is a precursor of a large number of lipid mediators, known collectively as eicosanoids, which have inflammatory properties. Prostaglandins,  $\text{TXA}_2$ , prostacyclin and leukotrienes are all eicosanoids and are liberated from various inflammatory cells, such as mast cells, eosinophils, basophils and macrophages. One route by which eicosanoids are produced is the cyclooxygenase pathway, which leads to the production of thromboxanes, prostaglandins and prostacyclin. Another major route for eicosanoid production is the leucocyte lipooxygenase pathway, which leads to the production of leukotrienes. The entity formerly known as slow-reacting substance of anaphylaxis belongs to this class of compound and is now known to comprise a number of different cysteinyl leukotrienes ( $\text{LTC}_4$ ,  $\text{LTD}_4$  and  $\text{LTE}_4$ ) [642]. A number of eicosanoids, particularly the

leukotrienes, probably play varying roles in the production of inflammation, mucous secretion and tissue injury. Steroids may have a limiting effect on these injurious events by suppressing the production of eicosanoids via both pathways of arachidonic acid metabolism (cyclooxygenase and leucocyte lipooxygenase). It is possible that this limitation is partly achieved through the glucocorticoid-stimulated release of inhibitory proteins such as lipocortin 1, arachidonic acid release being retarded by its inhibition of the enzyme phospholipase  $\text{A}_2$  [640,641,643,644]. Specific leukotriene modifying drugs have been referred to in the previous section and are the subject of current research.

#### ***Inhibition of platelet-activating factor***

In addition to various eicosanoids, platelet-activating factor (PAF) is another lipid inflammatory mediator that is less powerful *in vitro* than cysteinyl leukotrienes. It may also be released from inflammatory cells such as eosinophils and macrophages as a result of phospholipase  $\text{A}_2$  activity on cell membrane phospholipid precursors

[645,646]. PAF may be important in recruiting further eosinophils and may lead to a prolonged increase in bronchial hyperresponsiveness as well as microvascular leak in asthma. PAF is also inhibited as a result of the suppression of phospholipase A<sub>2</sub> by steroids. The experimental development of specific PAF antagonists has so far had disappointing results in asthma.

### *Inhibition of histamine release*

Histamine is one of the mediators of bronchoconstriction that is released by mast cells and basophils after both immediate IgE-mediated allergic reactions and following non-immune stimuli. It is a less potent mediator than leukotrienes *in vitro*. Of the three types of histamine receptor in the airways, H<sub>1</sub> stimulation causes bronchoconstriction, H<sub>2</sub> stimulation results in mucous secretion and there is animal evidence to suggest that H<sub>3</sub> receptors may be concerned with histamine release from mast cells. Although oral glucocorticoids do not affect the acute physiological response of allergen challenge to the lung, nasal passages or skin [647], steroids appear to suppress the IgE-mediated release of histamine from basophils [638]. Mast cell activity is probably reduced indirectly by steroids, which diminish the numbers of submucosal T lymphocytes, these in turn liberating interleukin cytokines that may have an inhibitory effect on mast cells [648]. Antihistamines such as the H<sub>1</sub> antagonists chlorphenamine (chlorpheniramine) and loratadine, although effective in allergic rhinitis, are disappointing in asthma.

### *Effects on vasculature*

Steroids act to reduce capillary permeability at sites of inflammation [649] and are potent inhibitors of inflammatory oedema. This can be beneficial in certain inflammatory conditions by preventing the passage of both inflammatory cells and immune complexes from the intravascular space to surrounding tissues. It is not known by what mechanisms steroids produce this effect on capillaries but the suppression of inflammatory mediators (see above), as well as cytokines such as tumour necrosis factor  $\alpha$  and fibroblast growth factors, may be involved. The production of a protein, other than lipocortin 1, that acts on endothelium to reduce permeability is suggested as another mechanism [650].

### *Cellular effects*

Changes in the proportions of the normal white cell constituents of circulating blood can be detected within a few hours of a dose of glucocorticoid. The blood neutrophil count is increased, in part due to increased bone marrow production. These cells are required for acute inflammation and steroids may inhibit their movement into

inflamed tissues, partly by blocking the production of recruitment cytokines, so that neutrophils are redistributed from the tissues back into the circulation [647,651]. Circulating eosinophils, basophils, monocytes and lymphocytes are all reduced [651,652], possibly as a result of their redistribution to other extravascular sites including lymphoid tissues, as fewer of these cells are to be found in inflamed tissues. A reduction in the numbers of tissue-based T lymphocytes is likely to be an important response to steroids, these cells being known to liberate cytokines such as interleukins, which probably play important roles in the activation of other inflammatory cells [647]. Such a reduction has been observed in the lungs of asthmatic patients treated with an inhaled steroid [653]. The suppression of the tuberculin reaction is a further example of the impairment of T cell-mediated immune responses by steroids. Seasonal increases in the numbers of nasal mucosal mast cells are attenuated by long-term administration of topical nasal steroids in patients with allergic rhinitis [654]. Similar observations have been made in the lungs of asthmatic patients treated with an inhaled steroid, not only for T lymphocytes and macrophages but also for mast cells and eosinophils [653]. Steroids may inhibit the proliferation of mucosal mast cells, although they do not inhibit the release of inflammatory mediators from mast cells once they have been challenged by antigen [647]. Activated eosinophils are known to be capable of liberating secretory products that are both cytotoxic to bronchial epithelial cells and that also increase bronchial smooth muscle responsiveness. There is evidence to suggest that treatment with steroids reduces eosinophil proliferation, differentiation and activation, probably indirectly by reducing cytokine production from T lymphocytes, macrophages and endothelial cells, all of which affect eosinophil function [647]. The recruitment of basophils is suppressed by steroids, probably by blocking various recruitment factors such as cytokines and PAF [647]. Thus in addition to alterations in the numbers of individual constituents of the intravascular white cell pool, steroids also inhibit a number of complex cellular functions that contribute to inflammatory or immunological processes.

### *Effects on $\beta_2$ -adrenergic receptors*

The increased sensitivity of  $\beta_2$ -adrenergic receptors to both endogenous catecholamines and to administered synthetic  $\beta_2$  agonists is an important effect of steroids in patients with asthma, becoming evident within about 1 h of intravenous administration [655]. The mechanism by which this occurs is uncertain, but it may involve the enhancement of chemical receptor synthesis or an increase in the sensitivity of existing receptors. The human  $\beta_2$ -adrenergic receptor gene is known to contain a number of GREs (see above) ready to interact with steroid-receptor

complexes, and it may be that  $\beta_2$ -receptor numbers increase as a result of steroids affecting gene transcription [648,656].

### Miscellaneous effects

Glucocorticoids may inhibit the growth of fibroblasts and therefore the laying down of collagen and 'scar tissue' as a consequence of inflammation. The mechanism is unclear, although cytokine downregulation, which may include a reduction in fibroblast growth factors, is possible. Steroids may also modulate calcium ion movements across cell membranes, a process important in the activation of the enzyme phospholipase  $A_2$ . They also modify the effects of many other inflammatory mediators too numerous to mention here but which are reviewed elsewhere [638,648,657]. They reduce bronchial hyperresponsiveness as a result of their anti-inflammatory actions in the airway and are therefore a cornerstone in the management of asthma [658] as well as many other less common inflammatory diseases of the lungs.

### Administration, metabolism, excretion

Corticosteroids are generally rapidly and almost completely absorbed when taken by mouth. They may be divided into short-, intermediate- and long-acting preparations in terms of the length of time that they suppress adrenocorticotrophin (ACTH) production. Hydrocortisone, cortisone, prednisolone, prednisone and methylprednisolone are regarded as short-acting. Triamcinolone is intermediate and both betamethasone and dexamethasone are longer-acting [659]. The majority of steroid preparations are also available for parenteral use, either as freely soluble and rapidly absorbed sodium phosphate or sodium succinate esters or as poorly soluble 'depot' preparations that are completely but slowly absorbed.

### Oral corticosteroid preparations

#### Prednisolone and prednisone

Prednisolone (Fig. 9.28) is a favoured oral steroid preparation. It is largely absorbed within 30 min of ingestion. Metabolism is primarily hepatic, with the production of inactive metabolites. The metabolism of prednisolone and other steroids is enhanced by hepatic enzyme-inducing drugs, such as phenobarbital (phenobarbitone), phenytoin, carbamazepine and rifampicin, so that these reduce the glucocorticoid effects of steroids. The opposite may result from liver disease or impairment of liver function as a result of metabolic disease; furthermore since prednisolone and other steroids are for the most part protein-bound, hypoalbuminaemia increases glucocorticoid activity and its attendant side-effects. The plasma half-life

Fig. 9.28 Structure of (a) prednisone and (b) its active metabolite prednisolone.

of prednisolone is about 3 h, whereas the physiological activity (based on duration of ACTH suppression) is about 20 h. Thus a once-daily dosage regimen may allow some degree of adrenal recovery from suppression before the next dose is due. By comparison, a once-daily dose of hydrocortisone (cortisol), of which an oral preparation exists, is not workable as its duration of action is too short. The inactive metabolites of prednisolone are excreted in the urine. Its pharmacokinetics do not vary significantly between night and day [660].

Prednisone is inactive since it is a prodrug with no glucocorticoid activity until it has been metabolized by reduction to prednisolone in the liver. However, this takes place rapidly so that its plasma half-life is only about 1 h. Its onset of action is bound to be slower than its metabolite prednisolone, which differs structurally in having a ketone rather than a hydroxyl group in the C-11 position. Nevertheless, the peak effect is reached after a similar length of time with both preparations and comparable levels of prednisolone appear in the plasma no matter which preparation is given, provided that liver function is normal. However, the same glucocorticoid activity may not be achieved in patients with liver disease, and prednisolone is pharmacologically preferred as the plasma levels achieved are unaffected by hepatic dysfunction [661]. Both these drugs have little mineralocorticoid activity by comparison with hydrocortisone and cortisone and are preferred in the longer term, other than for replacement in adrenal insufficiency. The prodrug prednisone is no longer commercially available in the UK.

*Cortisone and hydrocortisone*

Cortisone was the first naturally occurring corticosteroid to be used. Like prednisone, it is a prodrug that is inactive until converted to hydrocortisone (cortisol) by reduction in the liver, with the substitution of a hydroxyl group for a ketone group in the C-11 position (Fig. 9.29). It has similar pharmacokinetic properties to hydrocortisone, although dose for dose it is about 25% less potent with regard to glucocorticoid effect. Its traditional use was as replacement therapy in Addison's disease, a role for which hydrocortisone is now pharmacologically preferred, both drugs possessing mineralocorticoid as well as glucocorticoid activity.

*Methylprednisolone*

Methylprednisolone differs in structure from prednisolone only by the possession of a methyl group in the C-6 position of the steroid structure (Fig. 9.30). Dose for dose it has slightly greater glucocorticoid effect than prednisolone and little mineralocorticoid effect, which may be of clinical significance by reducing the chance of serious hypokalaemia if high-dose methylprednisolone is used. The speed of onset, peak effect and duration of action are broadly similar to those of prednisolone. Methylprednisolone has been shown to penetrate lung acini better than prednisolone and it has been proposed that this could have practical benefits in the management of potentially fibrotic lung disease [662,663]. This oral preparation is about 10 times the cost of prednisolone.

**Fig. 9.29** Structure of (a) cortisone and (b) its active metabolite hydrocortisone.

*Triamcinolone*

Triamcinolone differs in structure from prednisolone by the possession of a fluorine atom at the C-9 position and an additional hydroxyl group in the C-16 position (Fig. 9.31). The rate of absorption and peak effect are similar to those of prednisolone. Metabolism is also hepatic but slower, as with other fluorinated steroids (betamethasone and dexamethasone), so that its plasma half-life is over 3 h. Its duration of action is also longer and may be about 2 days. Dose for dose it has a slightly stronger glucocorticoid effect than prednisolone, being equivalent in this respect to methylprednisolone. Like betamethasone and dexamethasone it has no significant mineralocorticoid effect.

*Betamethasone*

Betamethasone, like triamcinolone, is a fluorinated steroid but differs from this compound by the possession of a methyl group in place of the hydroxyl group at the C-16 position (Fig. 9.32). The rate of absorption and peak effect are similar to prednisolone. Possession of the fluorine atom results in delayed hepatic metabolism and a plasma half-life of over 3 h. The duration of action of betamethasone is longer than that of triamcinolone and may exceed 3 days. The presence of the methyl group increases its glucocorticoid activity (including adverse effects), so that its potency in this respect is about five times that of prednisolone [664]. Mineralocorticoid effect, as with triamcinolone and dexamethasone, is said to be minimal [649].

**Fig. 9.30** Structure of methylprednisolone.

**Fig. 9.31** Structure of triamcinolone.

Fig. 9.32 Structure of betamethasone.

### Dexamethasone

Dexamethasone differs structurally from betamethasone only geometrically, in that the methyl group in the C-16 position is in the  $\alpha$  rather than the  $\beta$  position (Fig. 9.33). The rate of absorption and peak effect are similar to prednisolone. The plasma half-life is over 3 h because, like triamcinolone and betamethasone, its hepatic metabolism is slowed by the possession of a fluorine atom in the C-9 position. Its duration of action is similar to that of betamethasone. Weight for weight it also has similar glucocorticoid potency to betamethasone [58], this being about five times that of prednisolone. Mineralocorticoid effect is negligible, as is the case with methylprednisolone and the other two fluorinated corticosteroids triamcinolone and betamethasone. High-dose dexamethasone tends to be favoured in the palliative treatment of raised intracranial pressure due to brain metastases, in which case fluid retention and potassium loss due to mineralocorticoid effect would be a disadvantage.

### Deflazacort

Deflazacort is a more recently introduced orally administered steroid with glucocorticoid activity. It is an oxazoline derivative of prednisolone. Dose for dose it is slightly less potent than prednisolone, so that a 6-mg dose of deflazacort has a similar anti-inflammatory effect to 5 mg prednisolone. Claims that this compound may be less likely to cause steroid-related osteoporosis or diabetes mellitus require substantiation. It is about 20 times the cost of prednisolone.

### Parenteral corticosteroid preparations

#### Hydrocortisone

Hydrocortisone (cortisol) is a favoured short-term parenteral steroid preparation. Its structure is shown in Fig. 9.26. It is usually given intravenously, rather than intramuscularly, as the sodium succinate or sodium phosphate ester. Its onset of action, although more rapid than with prednisolone and other steroids, is by no means immedi-

Fig. 9.33 Structure of dexamethasone.

ate [665]. Its peak effect on airway mechanics may be achieved more rapidly, the time between administration and onset of benefit in asthma being thought to be about 5 h compared with about 8 h for prednisolone [666]. Dose for dose, hydrocortisone possesses slightly greater mineralocorticoid activity than prednisolone and this may have some additional benefit in the treatment of acute severe asthma in patients maintained on oral steroids and who may develop relative adrenal insufficiency in situations of stress. Conversely, oral hydrocortisone is avoided in the longer-term treatment of asthma as its mineralocorticoid activity would be more likely to cause fluid retention and potassium loss; indeed care needs to be taken to prevent severe hypokalaemia with associated ventricular tachycardia when high-dose hydrocortisone is given parenterally [667]. Hydrocortisone undergoes hepatic metabolism and its plasma half-life is 1–2 h, which is about half that of prednisolone. Its duration of action based on ACTH suppression is variable, depending on body size, and is about 8–12 h; this is about half that seen with prednisolone and necessitates multiple daily dosage or continuous infusion in asthma management.

#### Cortisone

Cortisone is not available as a parenteral formulation in the UK. A poorly soluble but slowly released and completely absorbed acetate derivative is available in the USA, but has no place in the management of respiratory disease.

#### Prednisolone and prednisone

Prednisolone is available as a poorly soluble acetate derivative for intramuscular depot injection, being slowly absorbed and remaining active for up to 3 weeks. A freely soluble sodium phosphate preparation is available in the USA for rapid-onset intravenous use and may also be given intramuscularly. The pharmacology has been discussed above.

#### Methylprednisolone

Methylprednisolone is available as a freely soluble

sodium succinate ester for intravenous or, less frequently, intramuscular use. The pharmacology is as described above for the oral preparation. A poorly soluble acetate derivative is also available. This intramuscular depot preparation is very slowly absorbed, so that it may take about a week to reach its peak effect and its duration of action may be up to 4 weeks. Pulse treatment, with depot methylprednisolone injections every 2 weeks, has been used in the past in the treatment of asthma [668], although high-dose pulse methylprednisolone is unlikely to be more effective than short-course oral prednisolone in this situation [669]. High-dose treatment with methylprednisolone or other steroids in critically ill patients with septic shock does not appear to prevent adult respiratory distress syndrome and is probably without benefit [670,671].

### *Triamcinolone*

Triamcinolone is available as a poorly soluble acetonide derivative for intramuscular depot injection, being very slowly absorbed. The peak plasma concentration may be achieved in 48 h, the level thereafter gradually declining to become undetectable at about 3 weeks [672]. Such depot injections have been successfully used once monthly in chronic asthmatics [673], the clinical effect lasting up to 6 weeks. A similar slow-release diacetate derivative is available in the USA for intramuscular use. There is no rapidly absorbable parenteral form. The pharmacology is as described above for the oral preparation.

### *Betamethasone*

Betamethasone is available as a freely soluble and rapid-onset sodium phosphate derivative for intravenous or, less frequently, intramuscular use. A mixture of betamethasone sodium phosphate and acetate derivatives is available in the USA for use as a depot intramuscular injection. No such poorly soluble derivatives are available in the UK. The pharmacology has been discussed above.

### *Dexamethasone*

Like betamethasone, dexamethasone is also available as a rapid-onset sodium phosphate derivative for intravenous or, less commonly, intramuscular use. No intramuscular depot preparation is available in the UK but a slow-release intramuscular acetate formulation exists in the USA that is intended for weekly to 3-weekly dosage.

### *Other parenteral preparations*

Other parenteral preparations that are not themselves corticosteroids but which cause corticosteroid release include ACTH, which is obtained from mammalian pituitary and

is no longer commercially available in the UK, and tetracosactrin, which is synthetic but structurally similar to ACTH. When given to a subject with responsive adrenal glands, these substances result in the endogenous production of hydrocortisone (cortisol). This pharmacological effect is useful in the investigation of adrenal function and is the basis of the tetracosactrin test. This effect has also been put to therapeutic use in the treatment of asthma and has been claimed to cause less growth suppression than exogenous corticosteroids in children [674], although the evidence for this is somewhat slender. Such treatment has a number of disadvantages:

- 1 it needs to be given parenterally and this tends to be less acceptable in children;
- 2 the pituitary–adrenal axis may be suppressed at a higher level, so that pituitary rather than adrenal suppression occurs;
- 3 previous treatment with exogenous corticosteroids may have caused adrenal suppression, with consequent lack of response to ACTH or tetracosactrin;
- 4 an undesirable mineralocorticoid effect, with salt and water retention, may occur;
- 5 when depot injections are used, release may be unpredictable and erratic.

Tetracosactrin acetate produces a peak plasma cortisol level 1 h after intramuscular injection, the level returning to basal conditions after 4 h. A more poorly soluble acetate/zinc phosphate complex derivative of tetracosactrin may be used for depot intramuscular administration, achieving a peak cortisol level at 8 h with raised values for over 24 h [675]. This preparation has been used in the treatment of asthma once or twice per week but the limitations in usefulness listed above apply. ACTH is no longer available in the UK but is still obtainable in the USA, being given either as a gelatin preparation subcutaneously or intramuscularly, producing an effect for 12–24 h. A zinc oxide preparation is given similarly and may have a duration of action of 48 h.

### **Dosage of systemic steroids**

This section is confined to general comments only and the reader is referred to chapters dealing with the management of specific diseases or clinical situations for more detailed recommendations about steroid dosage. Table 9.12 shows doses of various steroids with approximately equipotent anti-inflammatory (glucocorticoid) effects. Conversion factors for obtaining an approximately equipotent anti-inflammatory effect with the different drugs are shown in Table 9.13. Thus 30 mg of prednisolone, which is a commonly used starting dose for an oral course of steroid in moderate exacerbations of asthma, is equipotent to 120 mg of hydrocortisone. This order of dosage may achieve a maximum therapeutic response in asthma, although some patients may require

60mg daily to achieve the same effect, this dose corresponding to 240mg of hydrocortisone. For comparison, the baseline physiological requirement for hydrocortisone replacement in an adrenalectomized or Addisonian patient is 20–30mg daily. The practice of gradually reducing the dose of oral corticosteroid in the treatment of exacerbations of asthma has been criticized, and it has been claimed that 0.6mg/kg of prednisolone daily for up to 2weeks is an effective alternative [676], although this approach frequently causes worry and concern to patients who have been satisfied by their response to the earlier method. The standard 3mg/kg 6-hourly dose of hydrocortisone used in the treatment of acute severe asthma is intended to achieve a plasma cortisol level of 100µg/dL or more [677]. For a 70-kg patient, this amounts to 200mg hydrocortisone 6-hourly, which is equipotent to 50mg of prednisolone 6-hourly or 200mg daily. The 16mg dexamethasone daily that is conventionally used as a starting dose for the palliative treatment of cerebral metastases is equivalent to about 100mg of prednisolone daily, and so on. When treating patients with steroids, it is usual practice to start therapy with a high dose and to

gradually reduce once a satisfactory therapeutic response has been achieved. In many conditions a so-called ‘maintenance dose’ is continued, i.e. the dose at which control of the disease proves acceptably balanced against undesirable side-effects. In asthma of sufficient chronicity to require systemic steroids despite optimal inhaled therapy, this dose is frequently about 10mg prednisolone daily.

*Timing of steroid dose*

It is recommended that, whenever possible, oral steroids should be given as a single dose in the morning [678], the only exception being twice-daily physiological replacement therapy in adrenal insufficiency. This method of administration has been shown to be as effective as the same total dose divided through the day [679]. There are also a number of theoretical advantages: first, a morning dose coincides with the maximal physiological output of ACTH and should therefore be less likely to cause adrenal suppression and, secondly, steroids tend to be less protein-bound during the daytime and therefore more active [680].

It may be advisable, whenever possible, to try to administer steroids on alternate days by doubling the usual maintenance daily dose [681]. This manoeuvre is intended to reduce pituitary–adrenal suppression and to diminish other steroid-related side-effects but is not always possible in terms of disease control and may lead to problems with compliance [681]. The relatively short-acting steroids such as prednisolone lend themselves to this regimen, which will prove ineffective if long-acting preparations such as dexamethasone are used [682]. Alternate-day prednisolone therapy does not always prove possible in patients with chronic asthma, who may experience increased wheezing on the ‘off’ day [683]. However, it is applicable in other conditions such as sarcoidosis. Patients who have been on daily steroid treatment for a long time

may experience symptoms due to relative adrenal insufficiency on the 'off' day. This may be circumvented, if it is so wished, by introducing the change gradually, the dose on the intended 'on' day being steadily increased at the expense of dose on the 'off' day.

**Adverse effects of systemic steroids**

The general public are frequently aware, and not without good reason, that treatment with steroids is associated with unpleasant side-effects (Table 9.14). Those of which they are perhaps most aware are those that are medically least important but socially bothersome or distressing, such as a change in facial appearance and weight gain. The complete list of adverse effects is very long but fortunately some of these are either rare or their association only imperfectly established.

**Table 9.14** Adverse effects of steroids.

Cosmetic complaints
Facial fullness
Weight gain
Dependent oedema
Bruising
Atrophic skin
Striae
Acne
Bone complaints
Osteoporosis leading to fractures
Aseptic necrosis of the femoral head
Achilles tendon rupture
Dyspeptic symptoms
Peptic ulceration and complications
Ocular effects
Cataracts
Glaucoma
Benign intracranial hypertension
Mood change
Euphoria
Psychosis
Myopathy
Other metabolic and endocrine effects
Diabetes mellitus
Growth retardation
Salt and water retention
Hypokalaemic alkalosis
Hypothalamic–pituitary–adrenal axis suppression
Susceptibility to infection
Bacterial
Fungal (inc. candidiasis)
Viral
Adrenal insufficiency

For effects on pregnancy and lactation, see text.

The likelihood of side-effects from systemic steroid treatment depends on the size of the dose and the duration of treatment. Problems seldom occur with a short course of oral prednisolone, as used for asthma, started at a dose of about 30mg daily and continuing at this level or in reducing fashion for up to 2 weeks. Higher short-term dosage, usually in hospitalized patients, may be associated with untoward effects, as may maintenance doses taken for long periods as outpatient treatment. Adverse effects are also often more troublesome in the elderly. A community survey covering a population of 65786 subjects in the Nottingham area found that 0.5% were taking long-term (>3 months) steroids and that the steroids were being prescribed for respiratory conditions in 20% of cases (usually asthma/COPD), for polymyalgia rheumatica/temporal arteritis in 25% and for rheumatoid arthritis in 21% [684]. The prevalence of 0.5% rose to 1.7% in women aged 55 years or over.

The adverse effects of inhaled steroids are considered separately.

*Cosmetic complaints*

The most obvious of these to the patient is fullness of the face. The 'moon face' becomes evident to the physician after several weeks' treatment, usually with a dose of greater equivalence than 10mg of prednisolone daily, but may be noticed sooner by the patient and often persists to some extent, despite reduction of the dose to a lower maintenance level.

The patient also gains weight and should be warned to guard against the appetite-stimulating effects of steroids. This weight is typically gained centripetally, with the development of truncal obesity, although fluid retention due to mineralocorticoid effect plays a part and may produce dependent oedema in older patients. Weight gain may be associated with the appearance of striae. The older the patients, the more likely they are to complain of bruising. This is because elderly people bruise anyway and corticosteroids further increase capillary fragility, perhaps as a result of the atrophy of vascular supporting tissues. Cutaneous atrophy, which in extreme situations may produce shiny 'tissue-paper' thin and fragile skin, may be seen in elderly patients who have been taking maintenance steroids for months or years. Such a situation may result in the skin tearing with the least trauma, causing an unpleasant though superficial wound that may be slow to heal [685,686]. In the younger obese patient, cutaneous striae may appear on the trunk and proximal upper limbs, although these are rather uncommon and certainly less so than in primary Cushing's syndrome. Hirsutism is also less common in the iatrogenic form of Cushing's syndrome but tiresome acne may make an untimely reappearance in some adults.

### *Osteoporosis and other musculoskeletal disorders*

Treatment with glucocorticoids tends to produce a bone remodelling imbalance, both decreasing trabecular bone formation and increasing bone resorption, with resultant loss of bone density [687–689]. This leads to osteoporosis, which may be defined as a bone mineral density (BMD) score 2.5 standard deviations or more below the mean peak value in young (30–40 years) normal adults, osteopenia being said to be present at 1 standard deviation below the mean. The mechanisms are incompletely understood but it has been supposed that glucocorticoids primarily reduce new bone formation by inhibition of osteoblasts and that they also cause bone resorption, possibly by inducing secondary hyperparathyroidism as a result of impaired calcium absorption from the gut and renal tubules [688–690]. The result is a loss of up to 30% of trabecular bone in some cases, this being highest in the first 3–6 months of therapy. These effects often become clinically manifest in postmenopausal women and older men with the sudden onset of moderately severe and persistent back or girdle-type pain due to a collapsed dorsal vertebral body. Such compression fractures, which occur in about one-third of patients after 5–10 years of treatment [691], may be confirmed on spinal films or lateral chest radiographs. Chest pain may be due to a fractured rib caused by coughing and falls may result in femoral or other fractures. Whether or not intermittent courses of systemic steroids cause significant bone loss is unclear. It was estimated in 1993 that the annual cost of the consequences of osteoporosis to the community in England and Wales exceeded £500 million [684] so that it is regarded as an important public health problem.

The community survey covering a population of 65 786 subjects in the Nottingham area found that 0.5% were taking long-term (>3 months) steroids, that only 14% of such patients had been prescribed medication to treat or prevent osteoporosis and that only 10% of women over the age of 45 years on steroids in this group were taking hormone-replacement therapy [684]. Evidence of the efficacy of the various measures claimed to be effective for treating or preventing osteoporosis have been reviewed [688]. The encouragement of regular exercise, such as walking, and a dietary intake of 1500 mg calcium daily is recommended, with the addition of supplements as necessary in order to achieve this. Insoluble calcium salts such as carbonate have to be taken with food and are less well absorbed than soluble salts such as citrate; such supplements are more effective in preventing bone resorption if taken at bedtime. In older patients, heavy lifting should be avoided. Patients should be advised that both tobacco consumption and alcohol abuse are independent risk factors for the development of osteoporosis. Postmenopausal women are particularly at risk of osteoporosis

and treatment with estrogen replacement therapy is appropriate, compliance being enhanced by an explanation of the likely benefits and risks and, in appropriate cases, the use of a combined continuous estrogen–progestogen preparation in order to avoid uterine bleeding. Bisphosphonates, which may be regarded as ‘osteoclast poisons’, are an alternative and have also been shown to be effective in treating osteoporosis, for example cyclical etidronate 400 mg daily for 2 weeks followed by 500 mg supplemental calcium daily for 11 weeks or alendronate 10 mg daily taking care to follow instructions to avoid oesophagitis and ensure absorption. Oral vitamin D (800 iu daily) and calcium supplements are recommended in very elderly housebound or institutionalized patients, the effect of these various foregoing measures being to reduce the risk of fracture by about a half [692]. The active metabolite of vitamin D, calcitriol, and the related alfalcidol have been proposed as further alternatives, as has calcitonin.

There is a widespread assumption that such therapeutic or prophylactic interventions prevents corticosteroid-induced osteoporosis even though this is not certain. A 12-month, randomized, double blind, placebo-controlled trial involving 144 men and women taking at least 7.5 mg prednisolone or equivalent drug daily for at least 3 months, with ongoing treatment, has shown that cyclical etidronate and calcium prevents the loss of trochanteric and vertebral bone, on the basis of BMD assessment by dual-energy X-ray absorptiometry. New vertebral fractures were reduced by 40% in the treatment group at 1 year [693]. As high-dose systemic steroid treatment produces bone loss early, it is rational to introduce preventive interventions from the outset if it is expected that treatment will be prolonged [689]. It has been recommended that patients beginning long-term therapy with systemic steroids should ideally have the BMD of their lumbar spine measured at the onset. In young adults, those with bone densities at the lower end of, or below, the normal range should be offered preventive treatment, which should also be provided for elderly or postmenopausal patients [689].

Osteonecrosis refers to avascular necrosis of bone in which an impairment of the vascular supply to bone causes the death of osteocytes [694]. It may occur at any age, particularly in the third and fourth decades, and has a strong association with systemic steroid therapy, especially when high doses are used rather than small maintenance doses in the longer term. The mechanism is uncertain but it may be more common when steroids are used in conditions associated with vasculitis, such as systemic lupus erythematosus. Such aseptic necrosis affects the femoral head more frequently than other bones and collapse of the joint is often the consequence [695]. Patients may present with pain and limitation of movement in the

affected joint and in the case of femoral head involvement most require total hip replacement. It is fortunately rare and requires orthopaedic referral.

Non-traumatic Achilles tendon rupture may occur in patients taking systemic steroids. It can follow trivial exertion such as getting in or out of a car or simply walking on level ground. It produces local pain and swelling over the tendon and a discontinuity may be visible or palpable over the heel [696]. The affected gastrocnemius muscle may bulge proximally and bruising develops about the heel and foot. Degenerative changes occur in the Achilles tendon from the third decade onwards and it is assumed that these are made worse by steroid treatment, the condition usually occurring in patients taking long-term maintenance therapy [697]. The author has seen it occur bilaterally, with resultant total immobilization of a patient already severely limited by exertional dyspnoea. Management is orthopaedic, with heel raises, plaster of Paris, other forms of immobilization or open repair, should the patient be fit enough.

Two types of steroid myopathy are usually described. The more common chronic steroid myopathy occurs as a result of prolonged treatment with moderate doses and is characterized by the gradual onset of proximal limb muscle weakness, although respiratory muscles may also be affected [698,699]. This adverse effect is thought to be more troublesome with fluorinated steroids (triamcinolone, betamethasone, dexamethasone), which may selectively induce type IIb muscle fibre atrophy. The pathophysiology is unknown but a reduction in protein synthesis and the accumulation of glycogen are likely to be important. The condition reverses gradually on stopping the drug or with dosage reduction. An acute form of steroid myopathy is also described in which short-term treatment with high doses of steroid is thought to be causal. This form typically occurs with hydrocortisone in the course of treatment of respiratory failure with mechanical ventilation and is associated with diffuse weakness that includes the respiratory muscles [700,701]. It is unclear whether or not neuromuscular blocking agents contribute to this disorder, which appears to be related to the total dose of steroid. Degenerative changes may be shown on muscle biopsy and rhabdomyolysis may occur [698,702]. Both forms of myopathy occur in the absence of hypokalaemia and are unassociated with raised creatine kinase levels. There are occasional reports of muscle cramps occurring as a result of steroid therapy [700].

### *Dyspeptic symptoms*

It is common experience that patients taking corticosteroids orally may experience nausea and other upper gastrointestinal symptoms. It is also widely held that peptic ulceration may occur in such patients more frequently than would otherwise be the case, although this assumption

has been seriously questioned and no adequate prospective studies have been performed [704]. Retrospective studies using a variety of disease states requiring steroid treatment suggest a trend towards more peptic ulceration in steroid-treated groups, particularly in those receiving higher doses for longer periods of time [705,706]. A large case-control study in the USA showed that patients taking steroids doubled their chance of developing a peptic ulcer, although interestingly this risk was confined to patients who were taking concurrent non-steroidal anti-inflammatory drugs (NSAIDs). Patients who were taking steroids in the absence of NSAIDs had an incidence of peptic ulceration similar to the control population [707]. This leads to the conclusion that the simultaneous use of steroids and NSAIDs should be avoided if at all possible [708]. The beneficial effects of enteric-coated steroid tablets remains uncertain.

Complications of peptic ulceration, such as acute gastrointestinal haemorrhage or perforation, may occur with no particular antecedent symptoms, these being suppressed by the corticosteroid therapy itself. The situation may be further complicated by concurrent theophylline therapy, which may commonly cause nausea; furthermore, it is well recognized that peptic ulceration may occur in situations of stress due to any serious illness, respiratory or otherwise, and that it may occur during mechanical ventilation, whether steroids are used or not. Steroid-related upper gastrointestinal symptoms are frequently treated with  $H_2$ -receptor antagonists such as cimetidine or proton pump inhibitors such as lansoprazole. Such symptoms should ideally be investigated by endoscopy of the upper gastrointestinal tract. When peptic ulcers are found in patients who are taking steroids, there is no good evidence to suggest that they are less likely to heal or more likely to bleed or perforate than other peptic ulcers [709]. If cimetidine is used, it should not be forgotten that the half-life of oral theophylline may be doubled [710]. Pancreatitis may occur.

### *Ocular effects*

Cataracts are classified according to their location in the lens as nuclear, cortical or posterior subcapsular, the latter site being the most susceptible to metabolic insult, causing most visual loss and accounting for the majority of operative extractions, although with advancing age the other types increase in importance. The most common adverse ocular effect of systemic steroids is the formation of cataracts [711]. These are typically situated in the posterior part of the lens, immediately below the capsule and are usually bilateral [712]. Posterior subcapsular cataracts may be easily seen by the physician using an ordinary ophthalmoscope if it is held 15–20 cm from the patient's eye using a setting of +4 diopter (red or black number 4 on the wheel) and shows black against the red reflex and

moving opposite to the direction of the patient's gaze, as opposed to corneal opacities which move in the same direction [713]. Slit-lamp examination is more sensitive and is confirmatory. Cataracts in children are rare, but as with adults an association between the formation of posterior subcapsular cataract and prolonged systemic steroid therapy is recognized [714]. Although earlier studies showed no clear association, there is now good evidence that the use of inhaled steroids (see below) is indeed associated with the development of posterior subcapsular and nuclear cataracts in adults and that risk increases with larger dose and longer use [715]. The techniques used in a large community-based study of over 3000 subjects may actually have underestimated the true prevalence of cataract, which was three times higher in users of inhaled steroids [713]. No such association has yet been shown in children [716]. Raised intraocular pressure resulting in glaucoma has been described but is unusual. Rarely, benign intracranial hypertension occurs, sometimes following a reduction in steroid dose, young females being predominantly affected [717].

#### *Mood and neurological changes*

Corticosteroids have long been recognized to have a mild euphoric effect and this may be welcome. Unfortunately negative psychological changes with depression or anxiety may also sometimes be reported [718]. Occasionally, in large dosage, they may precipitate acute confusion and frank psychosis [719], much to the consternation of ward staff and patients alike. Such disturbances are fortunately uncommon and frequently no noticeable effect on psychological state occurs [720]. The control of epilepsy may deteriorate.

#### *Other metabolic and endocrine effects including growth*

Glucose intolerance is a well-recognized consequence of systemic steroid treatment [721], occurring either acutely during high-dose therapy, in which case insulin treatment may be required, or more insidiously where lower doses are concerned, in which case dietary regulation and oral hypoglycaemic therapy may suffice. The control of pre-existing diabetes invariably requires some adjustment.

Growth retardation [722] may occur in children, although the effect of the systemic steroid preparation itself is not always easy to separate from that of the disease for which the steroids are being prescribed [723–725]. Thus asthma in children may be associated with growth delay, often with a late onset of puberty, although in modern practice children with asthma usually attain a normal final height [726,727]. Discontinuance of therapy or a reduction in dose may allow growth to 'catch up' but this cannot be depended upon and it is accepted that the first priority is to control asthma effectively with

appropriate agents even if this entails the use of high doses. It has been concluded that slow growth in children is more likely to be caused by poor control of asthma than by treatment with inhaled steroids (see below) [728]. Hypothalamic–pituitary–adrenal axis suppression is discussed below.

Mineralocorticoid effects are a feature of the shorter-acting steroids and are exaggerated if the patient is also being ventilated mechanically. Sodium and water retention may precipitate or exacerbate heart failure and hypertension and high-dose steroid treatment may similarly produce significant potassium loss and a metabolic alkalosis.

#### *Increased susceptibility to infection*

Increased susceptibility to bacterial infection seldom seems to be a practical problem in patients other than those whose immune responses are separately suppressed by other factors, such as neoplastic disease and associated chemotherapy, in which case opportunistic infection is not uncommon. Certainly corticosteroids do suppress cell-mediated immune responses, and this has led to particular concern about their use in patients who may have had inadequately treated tuberculosis in the past. Such fears are not unjustified, although the probability of tuberculous reactivation seems to be low [729].

Relatively trivial fungal infection, such as oral candidiasis, is a well-known complication and the risk of serious systemic fungal infections is also increased, although such patients usually have other serious underlying disease and are otherwise immunocompromised.

Susceptibility to viral infection may also be increased and may become manifest by herpes-zoster infection, cold sores or cutaneous warts that sometimes defeat the best endeavours of the dermatologist.

#### *Effects on pregnancy and lactation*

Fertility is not necessarily reduced in patients taking systemic steroids. The occurrence of fetal abnormalities is also poorly documented and although common sense dictates the avoidance of systemic steroids if possible in the first trimester, pregnancy should not preclude their use in an urgent medical situation [730]. Animal experiments carried out nearly half a century ago produced a single report of an increased incidence of cleft palate in the offspring of rabbits treated with cortisone early in pregnancy [731]. Such an association has not been confirmed in pregnant women despite the use of systemic steroids for many years for a variety of disorders, nor is there good evidence of an increased incidence of other malformations or fetal harm [732,733]. Pregnant women who need systemic steroids can therefore be reassured and, in the case of asthma, usually accept the advice that the good health of

the fetus is best served by proper control of the mother's respiratory condition. The neonatal paediatrician needs to be aware that the mother has been taking steroids, although infantile adrenal suppression need not occur, possibly as a result of the protection of the fetus by placental inactivation of glucocorticoids. Doses of up to 40 mg of prednisolone or the equivalent may be taken daily by a lactating mother without hazard to the baby, especially if breast-feeding is delayed by 4 h after a single daily steroid dose [734].

### *Adrenal suppression and insufficiency*

The normal autoregulatory hypothalamic–pituitary–adrenal (HPA) axis is suppressed by the supraphysiological plasma levels of corticosteroids achieved when these agents are given systemically [735]. This results in reduced levels of corticotrophin-releasing hormone, produced by the hypothalamus, and ACTH, produced by the pituitary. In order to minimize HPA suppression, it is usual to give systemic steroids as a once-daily dose in the morning, since long-acting steroids and evening dosage regimens are more likely to produce HPA suppression [736]. HPA suppression may, in certain circumstances, result in the secondary failure of the adrenal glands to mount a response to various forms of 'stress', i.e. endogenous glucocorticoid output falls short of physiological requirements when exogenous steroids are withdrawn. Measurable HPA suppression may occur with high doses of inhaled steroids (see below) but is unlikely to be clinically important.

When short-course steroid therapy is used, for example in acute asthma, measurable HPA suppression may occur after the equivalent of 40 mg of prednisolone daily for 7 days or after 20–30 mg daily for up to 2 weeks [737,738]; however, this is only likely to present a potential problem for a few days after discontinuance and clinical difficulties are seldom encountered, so that it has become common practice to stop 2-week courses of 30 mg prednisolone daily (or equivalent) abruptly when this intervention is used in conditions such as asthma [737,739].

When longer-term treatment (>3 weeks) is used, the equivalent of 5 mg of prednisolone taken as a single morning dose need not cause HPA suppression [740], whereas supraphysiological doses (>7.5 mg prednisolone or equivalent) will. The data on such patients are not clear-cut but when long-term treatment with steroids is reduced, incremental dosage reductions should be relatively small and may be spread over the space of several months in order to allow the suppressed HPA axis to recover. Adrenal cortical recovery may take 12 months from the cessation of steroid therapy and during this period the patient may require exogenous steroids to cover periods of stress. A failure to meet this need may result in the development of symptoms of tiredness and

malaise, and in extreme cases hypotension and collapse with the features of Addisonian crisis. Such dramatic occurrences are rare but must be guarded against, as fatalities have occurred [741].

Various regimens of dosage reduction may be applied when a decision has been made to wean a patient off steroids [649,742]. Patients who have been given a trial of 40–60 mg prednisolone daily (or equivalent) for 1 month for conditions such as cryptogenic fibrosing alveolitis and who have failed to respond may be cut back to a dose of 15 mg daily in 2 weeks. Thereafter a 2-weekly reduction in the daily dose by 2.5 mg may be made until discontinuance. Patients who have been on steroids for longer periods of time for various conditions may need to be reduced more cautiously, particularly when it is unclear whether the disease for which the treatment was used has resolved or not. When a dose of 15 mg of prednisolone daily (or equivalent) has been achieved, further monthly decrements of 2.5 mg may be made down to 5 mg daily, after which slower decrements of 1 mg per month may be used to allow the HPA axis to recover. These tailing-off regimens may be implemented by using scored prednisolone 5-mg tablets (or enteric-coated 2.5-mg tablets) and 1-mg tablets. Clinicians should be aware that scored 25-mg prednisolone tablets are sometimes dispensed by pharmacists. These tailing-off regimens tend to be empirical and have to be tailored to the needs of individual patients.

It is recommended that patients who remain on systemic steroids for more than 3 weeks should carry a record of their dosages on a steroid card from the outset and those on long-term treatment may be advised to wear a 'medical-alert' bracelet or tag. Periods of moderate physical stress may be covered by temporary dose increases. Thus a patient taking a maintenance dose of 10 mg prednisolone daily for asthma who requires a cholecystectomy may be given 10 mg (or parenteral equivalent) preoperatively, followed by 50 mg hydrocortisone i.v. intraoperatively and 20 mg hydrocortisone i.v. 8-hourly on the first postoperative day, thereafter returning to their usual dose. Major surgical or other trauma in a patient taking 40 mg prednisolone may require treatment with hydrocortisone 50 mg 8-hourly i.v., reducing to the previous baseline dose after 2–3 days [743].

When doubt exists about whether the adrenals have regained their capability to respond to ACTH, a dynamic adrenal stimulation test is sometimes carried out, for example the short tetracosactrin (Synacthen) test in which an intravenous bolus dose of 250 µg of the ACTH analogue tetracosactrin is given. Hypersensitivity reactions, including anaphylaxis, have rarely been described with this test so that facilities for resuscitation should be available if it is used. For a normal result, the plasma cortisol prior to injection should be greater than 138 nmol/L (5 µg/dL) in a patient who has not received glucocorticoid for 12 h;

30 min after injection, the plasma cortisol should be greater than 500 nmol/L (18 µg/dL) and should have risen by at least 200 nmol/L (7 µg/dL). In practice this investigation is seldom necessary and indeed such tests of adrenal function are unfortunately not always good guides to the ability of the adrenals to respond to stress. A normal response to a short tetracosactrin test does not always guarantee normal adrenal function in the face of stress, although if the test is abnormal steroid cover for surgical procedures is certainly needed [742,743]. Single morning cortisol measurements alone cannot be relied upon as they show too much variability, even with strict standardization of collection time, and may be normal in 50% of patients with adrenal suppression due to episodic secretion [744].

At standard dosage, the systemic absorption of inhaled steroids (see below) is negligible, although at high doses evidence of adrenal suppression may be found. Although a potential hazard, in practical terms this seems to be of academic rather than clinical importance.

#### *Drug interactions with steroids*

Reduced therapeutic effects of corticosteroids may occur with the concomitant use of rifampicin, carbamazepine, phenytoin, phenobarbital (phenobarbitone), primidone and aminoglutethimide. A lack of awareness of such problems may result in a catastrophic loss of control when a rifampicin-based antituberculous regimen is started in patients with steroid-dependent asthma [745]. Steroids may enhance the hypokalaemic effect of diuretics. They tend to antagonize the effects of oral hypoglycaemic agents, hypotensive agents and diuretics.

#### *Avoidance of systemic steroid complications*

Physicians are generally well aware of the potential problems associated with corticosteroid therapy and make efforts to use the minimal effective dose, which varies in individual circumstances but which should, whenever possible, be gauged against some measured parameter of response according to the disease being treated. Such efforts are entirely rational, as adverse effects are related both to dose and duration of steroid therapy, which should be kept as short as reasonably possible.

When treatment is necessarily prolonged, long-acting fluorinated steroids should be avoided, since adverse metabolic effects may be more common and their greater potency makes fine dosage manipulation problematical. It may be possible to prescribe the short-acting corticosteroids used in maintenance therapy (prednisolone, methylprednisolone) on alternate days but at twice the equivalent daily dose [681]. This may produce a comparable therapeutic effect but tends to reduce both side-effects and the likelihood of HPA suppression. Patients with

asthma may experience worsening of their symptoms on the 'off' day, and those who have been on a stable daily maintenance dose for long periods may also be susceptible to adrenal insufficiency, often with weakness, joint pains and nausea on the 'off' day; thus transfer should be gradual by slowly increasing the dose on the 'on' day and reducing it on the 'off' day by a similar amount.

Whether oral steroids are used on a daily or alternate-day basis for maintenance therapy, they should be taken as a single morning dose since this may produce less HPA suppression and is as effective as divided doses.

#### **Inhaled steroids**

Early studies of inhaled steroids in the treatment of asthma were carried out in the 1950s using aerosolized agents such as hydrocortisone and dexamethasone in solution. These were disappointing, probably because of enzymatic inactivation, and no advantage over systemic preparations was demonstrated. The discovery that synthetic modifications to the basic steroid structure conferred topical anti-inflammatory (glucocorticoid) properties with little in the way of unwanted systemic effects was first put to use in dermatological practice with beclometasone (beclomethasone) dipropionate cream. The idea that a similar topical effect might result from the use of the aerosolized preparation was well demonstrated when beclometasone dipropionate became generally available as an MDI for the treatment of asthma in the UK in 1972. This and subsequent inhaled steroids have very high affinities for intracellular glucocorticoid receptors but are rapidly metabolized to biologically inactive compounds, with the result that they have a good topical anti-inflammatory effect on airways with relatively few adverse systemic effects. Any benefit from inhaled steroids in patients with COPD is likely to be small and of doubtful clinical significance, results from one international trial suggesting that abstinence from tobacco was likely to be more effective in reducing the rate of decline in FEV<sub>1</sub> than taking regular budesonide 400 µg twice daily, which had no significant effect on the overall rate of decline or indeed on symptom scores or the number of exacerbations [746].

#### *Advantages*

Inhaled steroids came to fill an important therapeutic gap in the treatment of asthma by reducing the symptoms of patients who were inadequately controlled on non-steroid therapy but whose symptoms were of insufficient severity to need systemic steroids. They also enabled some patients who might otherwise have required systemic steroids to remain off them and enabled those who did require systemic steroids to be maintained on a lower dose or to discontinue them altogether [74–750]. With the 'rediscovery'

that asthma is an inflammatory condition, there has been an increasing trend to use inhaled steroids at an earlier stage and it is now common practice to introduce them in asthma of sufficient nuisance to require dosage with  $\beta_2$  agonists more than once a day [658].

These advantages are achieved with few of those side-effects usually associated with systemic treatment (see above); furthermore at standard dosage, suppression of adrenal function does not occur and adrenal function returns in those patients in whom it is possible to discontinue previous systemic steroid treatment [751]. Patients should be warned that the onset of action is not immediate and that it may take a week or more to produce a beneficial effect. This conservative information reduces the chance of the abandonment of the preparation as ineffective. As with all inhalational devices, it is essential that the physician or a competent assistant demonstrates the technique for whichever delivery device is recommended and checks the patient's ability to carry out the necessary manoeuvre.

### Pharmacology

It is likely that the effective topical use of certain inhaled steroids results from the high surface activity achieved by esterification at the C-17 and/or C-21 positions and by the formation of C-16 and C-17 acetonide derivatives (Fig. 9.34). The molecular mechanisms are as described for systemic steroids above. Thus although the metered dose released from a delivery device is, for standard purposes, only measured in micrograms and although only about 10% of each dose reaches the lungs, nevertheless the topical potency of these inhaled steroids is such that a standard adult daily dose of 400  $\mu\text{g}$  beclometasone dipropionate is effective in asthma, to the extent of being equivalent in therapeutic efficacy to 5–12.5 mg of prednisolone [750,752,753].

### Mode of action

It is believed that the mode of action of inhaled topical steroids is broadly similar to that of their systemic

counterparts except that, for practical purposes, their actions at standard dosage are confined to the airways. By reducing airway inflammation, they diminish the airway hyperresponsiveness characteristic of asthma [658]. They have been shown to inhibit late allergic bronchoconstrictor reactions following an inhaled antigen challenge and, provided that several days' pretreatment is given, immediate reactions may also be inhibited [754,755]. They afford no immediate protection in exercise-induced asthma, although several weeks' pretreatment may have some protective effect in this respect [756].

### Absorption, metabolism and excretion

Up to 90% of each metered-dose inhalation may fail to reach the lungs, some being exhaled before deposition occurs but the bulk being deposited in the oropharynx, from where it is swallowed. In the case of beclometasone dipropionate, the small amount that reaches the lungs is rapidly absorbed into the blood [757]. The bulk of the drug is swallowed and is slowly absorbed, so that peak plasma levels occur 3–5 h after a dose [757,758]. It is likely that the small dose absorbed from the lungs is responsible for any potential systemic effects (such as adrenal suppression), since that fraction of the dose absorbed from the gut appears to be rapidly metabolized to inactive breakdown products during its first passage through the hepatic circulation [758,759]. These metabolites are for the most part excreted in bile and to a lesser extent in urine. The amount deposited in the mouth and subsequently swallowed is markedly reduced by the use of a large-volume spacer device attached to an MDI. A similar effect may be achieved by rinsing the mouth with water after using a dry powder delivery device.

### Method of administration

The original and most frequently used method of administration is pressurized MDI but there is a plethora of alternative dry powder delivery devices and spacers for the various preparations. It was at first recommended that inhaled steroids be taken in divided doses four times daily. As inhaled steroid treatment is essentially a preventive anti-inflammatory therapy, the patient receives no immediate signal of its efficacy, in contrast to  $\beta$  agonists in which a subjective response is usually rapid. This is disadvantageous with regard to patient compliance, so that treatments using less frequent dosage regimens were tested in order to increase the likelihood of the physician's advice being followed [760]. Twice-daily dosage regimens were shown to be as effective as the earlier four times daily regimens and are now standard [761,762]. This is the case for budesonide [763], beclometasone dipropionate [760,764] and fluticasone. It has been claimed that four times daily dosing may be more effective in severe asth-

**Fig. 9.34** Structure of beclometasone (beclomethasone) dipropionate: note dipropionate esterification in the C-17 and C-21 positions.

matics when high doses of inhaled steroid are used [765]. There is no convincing evidence that once-daily dosage regimens are as effective as the standard twice-daily approach [766,767].

#### *Dosage: standard or high*

Standard doses of inhaled topical steroids (equivalent to 400 µg of beclometasone dipropionate daily) have proved to be effective in the majority of patients with moderate asthma and early work with inhaled steroids showed no important improvement in the control of asthma with an increase in dosage of beclometasone from 400 to 800 µg daily [748], a finding that has been subsequently confirmed not only for beclometasone but also for budesonide [768,769]. Higher doses may be used with benefit in some patients with more severe asthma when the response to standard doses of inhaled steroid has been judged to be suboptimal [770]; studies that have examined the effects of higher doses on subsets of patients with more severe or chronic asthma have reported benefit with doses of beclometasone of up to 1000 or 1600 µg [771,772]. Similar claims have been made for high-dose budesonide (up to 1600 µg daily) compared with standard doses of beclometasone [773]. Needless to say, it may be misguided to prescribe higher-dose steroids before a check has been made to ensure that failure to respond to a lower dose was not due to poor inhaler technique [774]. An effort should also be made to demonstrate objective benefit if a high-dose regimen is to be continued. It should be remembered that the dose needed to maintain control may decrease [775], so that an attempt to reduce treatment may often be appropriate. All too frequently, patients may be left on an unnecessarily high dose of inhaled steroid in the longer term, a risk that may be increased by guidelines advocating initial treatment of asthma with high-dose inhaled steroids in order to gain rapid control, followed later by a step-down [776]. For most patients, the dose-response curve for airway efficacy becomes relatively flat at doses of inhaled steroid above 800–1000 µg daily [777], although the dose-response curve for systemic bioactivity and therefore any associated adverse effects becomes steep above this dose, particularly for steroids with greater systemic potency such as fluticasone propionate [778,779]. Some manufacturers have emphasized that their proprietary inhaled steroids may be inactivated by first-pass hepatic metabolism of the swallowed fraction of each metered dose, although it should not be forgotten that the dose which reaches the lungs is well absorbed directly into the systemic circulation and that this fraction assumes more importance with high-dose regimens. There is a risk that the uncritical use of high doses of inhaled steroid maximizes side-effects without increasing clinical benefit in many patients [780].

#### *Adverse effects*

The side-effects of inhaled steroids are relatively trivial and this, combined with their obvious therapeutic efficacy, has been the reason for their enormous success in the management of asthma.

Measures of HPA activity may be used as indicators of the systemic activity of topical steroids, being more sensitive in this regard than biochemical indices of bone metabolism [781]. HPA suppression equivalent to that encountered with maintenance alternate-day steroid therapy may be detected using such parameters [782]. These effects are minor and need not be regarded as indicating clinically significant impairment of adrenal function. When assessed by estimation of morning plasma cortisol or by 24-h urinary cortisol excretion, adrenal suppression in adults only occurs at doses of inhaled steroid exceeding the equivalent of about 1500 µg of beclometasone dipropionate daily [783–785]. The usual inhaled doses of other topical steroids, such as triamcinolone acetonide [786] and flunisolide [787], also seldom cause significant decreases in plasma cortisol levels.

From the standpoint of systemic activity, inhaled steroids should perhaps be used with more circumspection in children [782,788,789], although widespread and successful clinical use tends to belie such fears. Adrenal function was not found to be suppressed in children using either budesonide or fluticasone propionate at doses of 100–200 µg twice daily delivered by pressurized MDI via large-volume spacers, using overnight urinary cortisol as a marker [790]. It is possible that this result may be extrapolated to the budesonide dry powder device, bearing in mind that the respirable fraction from this is similar to that achieved with the pressurized device and large-volume spacer [790]. In general, in children doses of 400 µg beclometasone equivalent or less do not affect pituitary-adrenal function [658].

It should not be forgotten that patients who have received long-term treatment with systemic steroids only to be subsequently and successfully transferred to inhaled steroids may take about 12 months to recover normal responsiveness of their HPA axis and may therefore be susceptible to fatal secondary adrenal cortical insufficiency in any situations of stress that may occur during this period [791]. Although it has been suggested that patients taking inhaled steroids at doses equivalent to more than 1500 µg of beclometasone daily may need systemic steroids during prolonged stress [792], there is no evidence that such inhaled doses reduce a patient's capacity to produce endogenous cortisol in response to the stress of an attack of asthma [793]. The author is not aware of any published reports of adrenal crisis occurring as a result of the withdrawal of high-dose inhaled steroid therapy in either children or adults.

Whereas there is no doubt about the propensity of

systemic steroids to cause osteoporosis (see above), any links between inhaled steroids and altered bone metabolism are much more tenuous. Recent studies have been unable to reach consensus about whether steroids taken by the inhaled route have an effect on BMD, some showing a reduction in BMD [794], others not [795]. A recent cross-sectional study involving 81 patients found a reduction in lumbar spinal BMD in women equivalent to a reduction of about one-tenth of 1 standard deviation per 1000 µg/day inhaled steroid per year [794]. Such a seemingly small change would assume importance if any such relationship between reduced BMD and steroid usage was linear, since a number of studies have shown that the risk of vertebral fracture doubles for each standard deviation reduction in BMD [796]. No such relationship has so far been established.

The development of the technique of knemometry, which allows lower leg growth in children to be measured electronically with an accuracy of 0.2 mm, has demonstrated that inhaled steroids may indeed slow the rate of short-term growth [797,798]. This test appears to be a sensitive indicator of systemic activity since it has detected effects even when there has been no suppression of 24-h urinary cortisol; such changes have been shown with daily doses of 200–800 µg budesonide daily [799]. In another study, 400–800 µg beclometasone daily produced a greater effect on knemometry than fluticasone propionate 200 µg daily [800]. Although inhaled steroids may delay the onset of the prepubertal growth spurt in asthmatic children, there is good evidence that control of the asthma allows a subsequent 'catch-up' phase of growth to occur such that there is probably little difference in final adult height, which is likely to be compatible with that of their parents [801]. It is well known that asthma in children may be associated with growth delay, often with late onset of puberty, and it is accepted that the first priority is to control asthma effectively with appropriate agents even if this entails the use of high doses; indeed slow growth in children is more likely to be caused by poor control of asthma than by treatment with inhaled steroids [728,802]. In modern practice children with asthma who have been treated with inhaled steroids usually attain a normal final height [723,727,801].

A visible reminder that inhaled steroids are systemically absorbed is provided by the increased tendency of patients, particularly the elderly, to develop dermal thinning, striae and an increased tendency to bruise, especially when taking high doses [803,804].

Local side-effects of inhaled topical steroids include dysphonia and oropharyngeal candidiasis. Some degree of dysphonia has been reported in between one-third and one-half of patients taking inhaled steroids [805,806]. This may vary in intensity from a slight change in the quality of voice that is imperceptible to the observer and that the patient may not mention unless asked to obvious

hoarseness that regularly draws comment from social or casual contacts. Although at first attributed to candidiasis, visualization of the vocal cords in such patients has shown an adductor cord deformity in most cases [807]. It is now generally accepted that the dysphonia occurs as a result of a local steroid-induced myopathy affecting those intrinsic laryngeal muscles on which the steroid particles deposit during their passage through the oropharynx to the tracheobronchial tree. The frequency and severity of the complaint is related to the total daily inhaled steroid dose, tending to be more common with higher doses, although some patients may be badly affected in the lower dosage range [805]. Although a relatively minor nuisance to most patients, inhaled steroid-induced dysphonia may present a more serious problem to those who have to sing or who otherwise use their voices in their work. The dysphonia is reversible and disappears if the inhaled steroid is stopped [807]. The introduction of a spacer device (holding chamber) between the pressurized MDI and the patient's mouth undoubtedly reduces oropharyngeal deposition and therefore the incidence of candidiasis with inhaled steroids [808]. However, the use of these devices probably does not help to prevent dysphonia as they actually increase the proportion of the dose passing through the cords to the tracheobronchial tree [806,808]. There is evidence that some dry powder devices are less likely to cause dysphonia than pressurized MDIs, with or without spacers [809]. If this is the case, it may be that the anatomical position of the cords reduces laryngeal deposition of particles when the patient draws air through a resistance. Occasionally the inhaled steroid has to be reduced or temporarily discontinued altogether, provided that other medication is adjusted to allow for this. Unfortunately the problem often recurs.

Oropharyngeal candidiasis has been reported with inhaled steroid use, with widely varying frequencies of up to 77% [810]. However, such high figures are likely to be a consequence of the methodology of the study since *Candida albicans* may be recovered from the mouths and throats of 40–50% of control populations who are not taking predisposing medication [811]; it is presumably these patients, in whom the organism is established commensally before treatment, who are susceptible to develop the clinical syndrome of thrush. Although seemingly dose related when multiple inhalations from a lower-dose beclometasone pressurized MDI are used [748,772], the frequency of oropharyngeal candidiasis does not appear to increase in commensurate fashion when a higher dose is taken as a single inhalation using a 250 µg/puff MDI, implying that dosing frequency as well as total dose may affect the incidence [811]. The same may be true of budesonide [812]. There is no evidence that changing to a different steroid influences the risk. However, the delivery device is important and the use of large-volume plastic spacers with pressurized MDIs certainly diminishes the

risk of candidiasis by reducing oropharyngeal deposition from about 80% to about 20% [813,814]. The typical curd-like lesions on the tongue and oropharyngeal mucosa are easily recognized and treated with nystatin suspension (or pastilles) 100 000 units four times daily to be held in the mouth after food, continuing for 48 h after the lesions have resolved. Amphotericin 10 mg lozenges four to eight times daily for about 2 weeks may be used as an alternative. Such treatment is sometimes used empirically in the absence of obvious thrush if patients on inhaled steroids complain of soreness of the mouth. It is unusual for the inhaled steroid to have to be discontinued.

No long-term bronchial epithelial damage has been reported as a result of the use of inhaled steroids in conventional or high-dose form [815].

There have been occasional reports of inhaled steroids producing cough and wheeze in a few cases, with resultant patient intolerance [816]. Such difficulties, which in the author's experience are uncommon, could be a result of the propellant or dispersant rather than the steroid itself, in which case the use of an alternative pressurized MDI or dry powder device may overcome the problem [817,818].

### Individual inhaled steroid preparations

Although individual steroids have differing degrees of topical potency when tested on skin [819], the evidence that this provides one inhaled preparation with a clear therapeutic advantage over the next is slender, since at the recommended doses the different preparations available are approximately equivalent in terms of clinical efficacy. Failure of a patient to respond to one preparation is frequently due to poor compliance or technique. When this has led to patient disillusionment with a particular drug, a justifiable psychological ploy is to switch to another preparation and to ensure that the patient understands thoroughly how to use it properly.

#### *Beclometasone (beclomethasone) dipropionate*

Beclometasone dipropionate has a similar structure to dexamethasone except that it is halogenated, with a chlorine atom in the C-9 position and the C-16 methyl group in the  $\beta$  position (see Figs 9.33 & 9.34). The dipropionate derivative is formed by esterification of the hydroxyl groups in the C-17 and C-21 positions. Beclometasone is lipophilic, although less so than budesonide, flunisolide and fluticasone propionate, and the fraction absorbed from the gut is therefore susceptible to breakdown by P450 enzymes in the liver by first-pass metabolism. This is fortunate since it compensates for the ready systemic absorption of beclometasone and the other inhaled steroids from the mucosal surface of the lungs.

The standard adult dose by MDI is 200  $\mu$ g twice

daily (two 100  $\mu$ g puffs twice daily). 'High-dose' treatment usually comprises 500  $\mu$ g twice daily (two 250  $\mu$ g puffs twice daily) but doses of 1000  $\mu$ g twice daily may be used. Now that the product's patent has expired, a variety of standard and breath-actuated pressurized MDIs are available. The general principle is to use the lowest dose that controls the patient's symptoms adequately. This should mean that the vast majority of asthmatics in the community take the lower dosage range but that difficult cases may require the higher doses. These carry the risk of adverse systemic effects (see above), although to a lesser extent than an equivalent dose of oral steroid. Various dry powder preparations are available for those unable to operate pressurized MDIs (usually the very young and the elderly). A similar twice-daily regimen may be used, 400  $\mu$ g of dry powder being generally considered equivalent in effect to 200  $\mu$ g of the MDI preparation. Nasal aqueous sprays are available for the topical treatment of allergic rhinitis at a standard dose of 100  $\mu$ g twice daily to each nostril; these preparations are absorbed in similar fashion to inhaled steroids.

#### *Budesonide*

The structure of budesonide is shown in Fig. 9.35. It is non-halogenated (no chlorine or fluorine atom) and has acetone substitutions in the C-16 and C-17 positions. These substitutions increase its lipophilicity and pharmacological studies have shown that it has high topical potency with relatively low systemic activity [759,820]. As with fluticasone propionate and triamcinolone acetonide, the swallowed fraction of the inhaled dose undergoes a relatively high degree of first-pass metabolism in the liver (89%) so that systemic bioactivity is largely determined by the quantity of drug absorbed from the lung directly into the systemic circulation, thereby avoiding first-pass metabolism. The standard adult dose, as with beclometasone, is 200  $\mu$ g twice daily by pressurized MDI (*one* 200  $\mu$ g puff twice daily). Half this dose may be given in children using a 50- $\mu$ g MDI. 'High-dose' budesonide may be used up to 800  $\mu$ g twice daily. The same dose range may be delivered by a well-designed dry powder device. A formulation for nebulization is available (250–500  $\mu$ g/mL) but this is seldom indicated in adult practice. A nasal aerosol spray exists for the topical treatment of allergic rhinitis at a standard dose of 100  $\mu$ g twice daily to each nostril, reducing to once daily when control is achieved; these preparations are absorbed systemically in similar fashion to inhaled steroids.

#### *Fluticasone propionate*

Fluticasone propionate is a synthetic trifluorinated glucocorticoid, the molecular structure of which is shown in Fig. 9.36. It is highly lipophilic and therefore has very high

Fig. 9.35 Structures of the two epimers that comprise budesonide.

steroid receptor affinity, so that two puffs from a standard 50 µg/puff inhaler twice daily is, for practical purposes, equivalent to 200 µg twice daily of beclometasone or budesonide [821]. The 125-µg MDI may be considered equivalent dose for dose to the 250-µg beclometasone device. The greater potency weight for weight of fluticasone does not imply that asthma will be better controlled at optimal daily dosage. There is also a 250-µg pressurized MDI which has no equivalent beclometasone device. Fluticasone is licensed for dose regimens of up to 1 mg twice daily, which is equivalent to eight 250-µg doses of beclometasone twice daily, a fact that may not be appreciated in community prescribing. Fluticasone has a long plasma elimination half-life of about 14.5 h (cf. 2.3 h for budesonide). As with budesonide and triamcinolone acetonide, the swallowed fraction of the inhaled dose undergoes a high degree of first-pass metabolism in the liver (99%) so that systemic bioactivity is largely determined by the quantity of drug absorbed from the lung directly into the systemic circulation, thereby avoiding first-pass metabolism. The drug may be prescribed as pressurized MDI or dry powder. A nasal aqueous spray is available for the topical treatment of allergic rhinitis at a standard dose of 100 µg (two sprays) once or twice daily to each nostril;

Fig. 9.36 Structure of fluticasone propionate.

these preparations are absorbed in similar fashion to inhaled steroids.

#### Flunisolide

This preparation is available for the treatment of asthma as an MDI in the USA but not in the UK. Its structure differs from hydrocortisone in that it has a fluorine atom in the C-6 position and acetonide substitutions in the C-16 and C-17 positions (Fig. 9.37). It differs from triamcinolone only in the position of its fluorine atom. The dose is 500–1000 µg twice daily (two to four 250-µg puffs). Although absorption of this product is greater, as with budesonide first-pass hepatic metabolism is rapid with this compound [822]. A metered-dose nasal spray is available (also in the UK) for the treatment of allergic rhinitis, the usual dose being 50 µg (two sprays) to each nostril twice daily, topical glucocorticoids having been shown to be effective in blocking the nasal response to antigen challenge [823].

#### Triamcinolone acetonide

This compound (Fig. 9.37) is available for inhalation in the USA as an MDI but not in the UK. As with fluticasone propionate and budesonide, the swallowed fraction of the inhaled dose undergoes a relatively high degree of first-pass metabolism in the liver so that systemic bioactivity is largely determined by the quantity of drug absorbed from the lung directly into the systemic circulation, thereby avoiding first-pass metabolism. The dose per puff is 200 µg, although a spacer device allows only 100 µg to reach the patient. The standard dose is eight inhalations daily given in divided doses at least twice daily. Up to 16 doses daily may be used in 'high-dose' therapy. A nasal aqueous spray is available for the topical treatment of allergic rhinitis at a standard dose of 110 µg (two sprays)

**Fig. 9.37** Structure of (a) triamcinolone acetonide (note acetonide group attached to C-16 and C-17 positions) and (b) flunisolide (differs only in position of fluorine atom).

once daily to each nostril, reducing to one spray when control has been achieved; these preparations are absorbed in similar fashion to inhaled steroids.

### Delivery devices for inhaled medication

It is beyond the scope of this chapter to describe the large number of devices commercially available for the delivery of inhaled bronchodilators and anti-inflammatory drugs. The two main categories are pressurized MDIs and dry powder devices [437]. The first category has been refined with the introduction of breath-actuated devices that do away with the need to coordinate finger and diaphragm and may be used in place of the standard 'press and breath' inhalers. Many of the 'press and breath' inhalers may be used with large-volume spacer devices designed to reduce oropharyngeal impaction and to generally reduce the need for coordination [824]. There are also many different dry powder devices, ranging from simple 'capsule in chamber' arrangements and blister packs or strips to cunningly engineered twist-loading turbine devices. Some manufacturers produce attachments for their devices in order to assist the patient who has difficulties actuating or loading the inhaler because of a weak grip. Suffice to say that no one inhaler device reigns supreme. Many patients are able to manage the original 'press and breath' devices adequately. Other patients may cope better with a device that requires simple suction. It is a matter for the doctor or nurse to first familiarize themselves with the alternatives and to be prepared to spend time teaching whichever technique the individual patient seems most comfortable with and best able to manage [437,825].

Jet nebulizers are the delivery mechanism of choice for bronchodilators in acute severe asthma affecting all age groups, and have the added advantage that they may be driven by oxygen. The jet of driving gas draws the solution to be nebulized up a fine-bore tube using the venturi principle. The solution is then fragmented into small droplets by impact with a baffle, the remaining solution

falling back into the reservoir of the nebulizer to repeat the cycle until all is used up. The mass and volume distribution of particles produced by different nebulizers varies according to the characteristics of the jet nebulizer, the compressor, the rate of flow of driving gas and the volume of fill [437].

### Chlorofluorocarbons (freons) and the Montreal Protocol

Under the terms of an international agreement known as the Montreal Protocol, 140 countries agreed to phase out their entire use of chlorofluorocarbons (CFCs) in order to diminish damage to the earth's stratospheric ozone layer. One effect of this agreement has been the gradual replacement of CFC propellants in pressurized MDIs with hydrofluoroalkane (HFA) alternatives; rather than chlorine these contain fluorine, which does not deplete the ozone layer. It is probable that the transition will be completed within the first 5 years or so of the twenty-first century. The first salbutamol HFA formulation has somewhat different physical characteristics and the patient may notice these in terms of the impact of the spray and the slightly different taste, but the formulations may be substituted dose for dose. However, there are preliminary data indicating that some HFA steroid formulations have markedly different characteristics, with a smaller particle size resulting in a greater fractional deposition of steroid in the lungs with less being swallowed, to the extent that it may be desirable to step *down* the dose of inhaled steroid when the change is made from CFC to HFA in order to achieve the same bronchial effect. Thus one proprietary beclomethasone product will have approximately the same clinical effect for half the dose [826]. Such changes may reduce the importance of first-pass metabolism in the liver and increase the importance of direct systemic absorption from the lungs. The trend is therefore likely to be one of dose reduction, depending on the physical characteristics of individual delivery devices as they become available, and it may help to focus the medical profession on the opportunity to reduce inhaled steroid treatment.

## Respiratory stimulants

Many drugs are known to stimulate ventilation in humans but few have found a place in therapeutics, largely because of their high incidence of toxic side-effects, a prime example being strychnine. A description of some drugs that have found, or may yet find, a useful clinical role follows.

### Analeptic drugs: doxapram

Three analeptic drugs were available for intravenous administration at the time of the last edition of this book: doxapram, nikethamide and ethamivan. Of these, only doxapram remains commercially available in the UK and USA. The principal, if limited, role of this drug is in the short-term management of acute ventilatory failure, usually in patients with chronic bronchitis and emphysema, as an addition to the more usual interventions such as bronchodilators and controlled oxygen therapy. The clinical situation in which this drug is applied is where the seriously hypoxic patient is starting to become obtunded and is displaying increasing evidence of alveolar hypoventilation, with a rising  $P_{aCO_2}$  and shallow irregular breathing. The use of a respiratory stimulant in these circumstances may rouse the patient's conscious level, enabling better clearance of respiratory secretions and improving minute ventilation [827,828]. Analeptic drugs are of no value in the treatment of an alert and anxious patient who is already fighting for breath, and may indeed be harmful in such circumstances, possibly resulting in increased metabolic production of carbon dioxide, without usefully adding to an already seemingly maximal ventilatory drive. Beneficial effects from the use of respiratory stimulants cannot be relied upon and if it is judged that mechanical ventilation (either nasal/face mask or by endotracheal intubation) is indicated, then this form of treatment is probably best prepared for without delay. If for some reason mechanical ventilation is thought to be contraindicated, if it is not immediately available for reasons of limited resource or if there is doubt about whether it will be necessary, then doxapram may be worth a trial [829]. Doxapram has also been used to treat respiratory depression following general anaesthesia [830].

### Mode of action, administration and pharmacokinetics

Analeptics are CNS stimulants, although at therapeutic doses doxapram acts on carotid body chemoreceptors [831]. Tidal volume and respiratory rate have been shown to be increased in healthy volunteers and ventilatory response to hypoxia and hypercarbia are heightened [831,832].

All analeptic drugs have to be given intravenously and

the duration of their action following injection is short, seldom exceeding 10 min. Nikethamide and ethamivan used to be given by slow bolus injection, whereas doxapram is normally given by infusion in the setting of acute respiratory failure due to chronic bronchitis and emphysema. There are no good data about whether repeated intravenous injection or continuous infusion is best, but the latter is usually preferred.

All these agents are rapidly metabolized and excretion of inactive metabolites is largely renal. Only a small proportion of doxapram is excreted unchanged in the urine, metabolism being largely hepatic [833].

### Dosage

Doxapram hydrochloride is available as a 2 mg/mL solution in 5% glucose contained in a 500-mL infusion bottle. An initial dose of 5 mg/min has been recommended, reducing according to response to a maintenance dose of 1–3 mg/min. Therapy should be controlled by blood gas and pH analysis. Limitation of the total dose to about 600 mg is advised. Nikethamide was given at a dose of 500 µg by slow intravenous injection, to be repeated at 30-min intervals according to response.

### Adverse effects

Analeptic drugs have a narrow therapeutic index, their effects extending from the desirable increased sense of wakefulness to undesirable CNS stimulation, including agitation, restlessness and in the worst case major convulsions; thus dose control must be careful and these drugs are contraindicated in epilepsy. Clearly a grand mal seizure in an already seriously hypoxic and hypercapnic patient with a depressed respiratory rate may deliver the *coup de grâce* and should be avoided at all costs; indeed it is for this reason that nikethamide and ethamivan are no longer recommended. Analeptics may also have a pressor and dysrhythmic effect as a result of increased epinephrine (adrenaline) release, so that hypertension and known coronary artery disease are relative contraindications.

### Progestogens: medroxyprogesterone acetate

An association between high levels of endogenous progesterone production in pregnancy and increasing ventilation has long been recognized [834] and can be demonstrated in terms of both increased minute ventilation and mouth occlusion pressure [835]. Similar respiratory stimulation may be induced by the administration of synthetic progesterone analogues such as medroxyprogesterone acetate. Minute ventilation rises as a result of an increased tidal volume and in normal subjects has been shown to result in a mean fall in  $P_{aCO_2}$  of about 0.7 kPa (5 mmHg) within

approximately 2 days [836]. It has been supposed that progesterone has a central action, crossing the blood-brain barrier and stimulating the brainstem respiratory centres, although this is uncertain [836]. Some workers have also found that progesterone may increase ventilatory responses to both hypoxia and hypercarbia [837–839].

There were early reports of medroxyprogesterone acetate having been used with evident clinical success in the treatment of patients with what was then thought to be hypercapnia due to primary alveolar hypoventilation occurring in association with obesity and hypersomnolence (previously known as pickwickian syndrome) [840,841]. Clinical improvement, in terms of reduced daytime somnolence and diminished heart failure, was also reported in some obese patients with what later became recognized as obstructive sleep apnoea syndrome; however, there was no significant diminution of episodes of potentially serious nocturnal arterial hypoxaemia or cardiac dysrhythmias in this study [842]. Subsequent experience with medroxyprogesterone in obstructive sleep apnoea syndrome was disappointing [843], this being predictable in view of the mechanical nature of the obstruction, which is now usually successfully overcome with continuous positive airway pressure or other measures (see Chapter 47).

A number of small studies have been carried out to assess the effect of medroxyprogesterone in patients with respiratory failure due to COPD. One such study examined the effect in 17 patients who were in chronic but stable respiratory failure with a mean  $FEV_1$  of 1.2 L,  $Pao_2$  6.6 kPa (50 mmHg) and  $Paco_2$  6.9 kPa (52 mmHg). A mean fall in  $Paco_2$  of about 1 kPa with a mean rise in  $Pao_2$  of about 0.7 kPa at 4 weeks was found in 10 of the patients [844]. Three other studies in patients with hypercapnic COPD have also shown mean falls in  $Paco_2$  with medroxyprogesterone, usually of about 1 kPa over the space of 1–4 weeks [845–847]. These other studies also reported modest improvements in oxygenation although, not surprisingly, this was not necessarily maintained at night [845]. It may be possible to predict which of this category of patients will respond by seeing whether they are capable of voluntarily lowering their  $Paco_2$  by deliberately trying to overbreathe [844].

Medroxyprogesterone acetate is well absorbed following oral administration, doses used having varied between 20 mg three times daily and 50 mg twice daily. Preparations available include 10 mg and scored 100 mg tablets (which are used for menstrual irregularities and the hormonal treatment of metastatic breast, endometrial and other hormone-sensitive cancers). The drug is mainly metabolized in the liver but significant amounts are excreted unchanged in the urine.

Adverse effects are uncommon but may include male

impotence and alopecia, fluid retention, weight gain and menstrual irregularities correctable with testosterone or cessation of the drug. There is a theoretical risk of thromboembolic disorders.

There is no good evidence to support the general or long-term use of this drug as a respiratory stimulant and whether there might be a case for its occasional shorter-term use during the stabilization of hypercapnic patients with diminished respiratory drive is still open to debate.

### Protriptyline

Protriptyline is a tricyclic antidepressant that has relatively little sedative effect. It is not a true respiratory stimulant in that it appears to have no effect on waking ventilation in normal subjects [848], although small doses appear to affect the pattern of breathing during sleep, tending to reduce the time spent in the rapid eye movement (REM) phase [849]. This effect is probably relevant to the benefit that has been recorded following its use in some patients with obstructive sleep apnoea syndrome [849,850]. Its mode of action is uncertain but it may modify upper airway motor activity via an effect on the brainstem reticular system, so that upper airway resistance is reduced [851]. There is some evidence to suggest that the centrally acting selective serotonin reuptake inhibitor fluoxetine also decreases the proportion of REM sleep and that some patients with obstructive sleep apnoea syndrome may similarly derive benefit, with fewer adverse effects than protriptyline [852]. Small studies in which it has been used in patients with hypercapnic respiratory failure due to COPD have shown increases in mean  $Pao_2$  and reduced nocturnal desaturation [853,854], although no improvement was found in daytime arterial oxygen concentration in a placebo-controlled double-blind trial of 10 mg protriptyline daily [855]. It may be given as a single dose 1 h before retiring, starting at 5 mg and gradually increasing to 20 mg according to response. Its usefulness may be limited by atropine-like side-effects, including dry mouth, constipation and urinary hesitancy. As with other tricyclics cardiac dysrhythmias may occur.

As with medroxyprogesterone, there is no good evidence to support the general or long-term use of this drug solely as a respiratory stimulant and whether there might be a case for its occasional shorter-term use during the stabilization of hypercapnic patients with diminished respiratory drive and in the more medium term for improving sleep quality is open to debate [853].

### Acetazolamide

Acetazolamide is a sulphonamide that reversibly inhibits the enzyme carbonic anhydrase. The primary site of action of the drug is the kidneys, where it inhibits renal tubular

hydrogen ion excretion, increasing urinary bicarbonate and decreasing urinary chloride concentrations [856]. Such changes reduce the extracellular fluid bicarbonate concentration, producing a metabolic acidosis with resultant stimulation of both medullary and peripheral chemoreceptors. These actions may prove clinically useful in patients with COPD, who may develop hypoventilation to compensate for a diuretic- or steroid-induced metabolic alkalosis. A double-blind placebo-controlled study assessing the effect of acetazolamide 250 mg twice daily over 1 week in a group of 53 hypoxaemic patients with COPD found that it produced a small fall in daytime  $P_{aCO_2}$ , a small increase in daytime  $P_{aO_2}$  and increased ventilatory responses to both hypercapnia and hypoxia [857]. There is also some evidence that the drug reduces periods of apnoea and arousals in central sleep apnoea [858,859].

Acetazolamide may also be used by mountaineers and trekkers as a means of helping to prevent acute mountain sickness by counteracting the hypoventilation that may develop following overbreathing caused by an excessively rapid ascent to high altitudes [860,861], hypoxaemia being particularly exaggerated during REM sleep at night [862].

The usual dose is 250 mg orally twice daily or 500 mg as two sustained-release capsules once daily; 250 mg 1 h before bedtime has been used in central sleep apnoea [859].

Side-effects include a mild diuretic effect with a predisposition to hypokalaemia. Paraesthesiae are also common. Sulphonamide adverse effects may occur and these can include agranulocytosis, so that blood counts are recommended if treatment is to be prolonged. Diclofenamide (dichlorophenamide) is an alternative carbonic anhydrase inhibitor available in the USA [863].

### Other drugs with respiratory stimulant properties

#### *Theophyllines*

Theophyllines are widely used for their bronchodilator properties and have been discussed fully in this context in an earlier section of this chapter. There has also been some interest in the ability of theophylline to stimulate respiration centrally and improve the contractility of the diaphragm and reduce its fatigue [547,864,865]. The clinical significance of these physiological observations in adults has been questioned [866], although in paediatric practice apnoeic episodes have been reduced in premature infants by theophylline administration [867].

Some but not all studies in normal subjects have found that intravenous aminophylline or therapeutic oral doses of theophylline increase minute ventilation, presumably as a result of a central effect [868]. It is doubtful whether any such respiratory stimulant effect is likely to be of clinical

significance in patients with COPD and the rationale for prescribing this group of drugs is to make use of their bronchodilator properties.

#### *Almitrine bimesylate*

Almitrine is a respiratory stimulant chemically related to the antihelminthic drug piperazine rather than to doxapram and other analeptic drugs. It has the apparent advantages of both oral administration and a long duration of action. The mode of action of this drug has yet to be fully defined but unlike other respiratory stimulants it acts peripherally on carotid and aortic body chemoreceptors with no effect on the central medullary respiratory centres [869,870]. There is little change in resting ventilation in normal subjects but the ventilatory response to hypoxia is greatly enhanced [871,872], that to hypercarbia being heightened to a lesser extent. In addition to increasing ventilatory responses [873,874], almitrine also improves ventilation-perfusion matching in patients with chronic bronchitis and emphysema, although it is unclear whether this is the result of a pulmonary vasoconstrictor effect [875–877]. The summation of these effects tends to increase  $P_{aO_2}$  and reduce  $P_{aCO_2}$  in such patients.

Almitrine is rapidly absorbed following oral administration. It is metabolized in the liver to largely inactive metabolites, the majority being excreted in bile and less than 5% in urine [878]. The plasma half-life after a single dose is 2–3 h but with increasing duration of therapy becomes gradually prolonged to well over 2 weeks, presumably as a result of its binding to tissues with subsequent slow release [879,880].

The indications for almitrine are still under investigation and whether it has a place in the treatment of hypoxic patients with COPD remains *sub judice*. Readers may wish to draw their own conclusions when considering that this drug has been under investigation for over 25 years and is still without a licence for general clinical use. A small early study suggested that as well as improving blood gas tensions during wakefulness, the frequency and severity of episodes of nocturnal hypoxaemia tended to be reduced [881], while other work suggested that a treated group of chronic bronchitics required fewer hospital admissions during the period of study. It was noticed in these early studies that some patients complained of worsening dyspnoea [879], paraesthesiae and peripheral neuropathy having been reported in other studies [882,883].

A larger prospective study examined the effect of almitrine 50–100 mg twice daily compared with placebo in over 700 patients with stable hypoxic COPD for up to 1 year in order to determine whether the drug had a role as a long-term treatment in this group, just as long-term oxygen therapy had been previously investigated in similar groups [884]. There was no survival advantage but the mean  $P_{aO_2}$  in the actively treated group improved by

about 1 kPa, with a smaller fall in  $P_{aCO_2}$  [884]. The treated group also had fewer hospital admissions, a reduction in secondary polycythaemia, a small rise in  $FEV_1$  but no change in 6-min walking distance [884]. About one-third of patients in the treatment group failed to respond. Improvement in these measured parameters was offset by a troublesome side-effect profile, with malaise, gastrointestinal upsets, loss of weight, increased dyspnoea and peripheral neuropathy; there was also a 40% withdrawal from the active limb of the trial compared with 25% with placebo [884]. These difficulties correlated with raised blood levels of the drug, resulting from its tendency to accumulate with prolonged use, so that a later UK study attempted to address this by adopting a regimen of 25–50 mg twice daily (1 mg/kg daily) for 2 months followed by a 1-month 'rest period' [885]. Small changes in arterial gas tensions were found similar to those of the earlier larger study, but there was no change in 6-min walking distance. The fall-out rate for the active treatment limb was 28% compared with 20% for placebo. Increased dyspnoea, gastrointestinal disturbance and paraesthesiae were equally cited, although no patient was thought to develop clinical peripheral neuropathy [885]. A study designed to evaluate the effect of short-term oral almitrine in addition to usual measures in patients admitted to hospital with acute-on-chronic respiratory failure due to COPD failed to show any benefit [886]. It is not known whether the addition of almitrine to long-term oxygen therapy in patients with COPD confers any benefit [880].

Small studies intended to examine the effect of almitrine on nocturnal oxygen saturation in patients with COPD have shown that just as this drug increases baseline  $P_{aO_2}$  during the day, so baseline  $S_{aO_2}$  is similarly increased at night [881]. In the short term, almitrine 1.5 mg/kg daily was found to be more effective in increasing nocturnal  $S_{aO_2}$  than 100 mg medroxyprogesterone in a similar group of patients with COPD [839].

There is no clearly defined role for almitrine in the management of central sleep apnoea [887,888].

## Cytotoxic drugs used in respiratory medicine

Cytotoxic drugs may be used in respiratory medicine both in the management of non-neoplastic disease in which there is some disturbance of immune regulation and in neoplastic disease. Non-neoplastic disease is more usually treated using corticosteroid therapy alone, other cytotoxic/immunosuppressive drugs being held as second-line treatment following the failure of steroids or are added for their steroid-sparing effect. There are exceptions to this general rule, such as Wegener's granulomatosis, other vasculitides and Goodpasture's syndrome. The drugs most commonly used in such non-neoplastic diseases are, in descending order of frequency, cyclophos-

phamide, azathioprine and chlorambucil, the use of cyclosporin being largely confined to transplant work.

Many cytotoxic drugs have been used in the treatment of intrathoracic neoplastic disease. The most notable successes have been scored in certain intrathoracic germ cell tumours, in lymphomas (especially Hodgkin's disease) and, to a much lesser extent, in small-cell lung cancer. The appropriate use of cytotoxic drugs in non-small-cell lung cancer remains controversial and continues to be examined, there being a need for randomized clinical trials to establish optimal management for this common group of diseases. These trials will have to be large in order to demonstrate anticipated improvements in median survival in the order of a few percentage points; although this appears to be a small difference, it might nevertheless make a significant impact on a common cancer, provided that a satisfactory quality of life could be maintained [889]. Such trials are still possible in the UK, where the scepticism of respiratory physicians for the value of chemotherapy in non-small-cell lung cancer has prevented its general use, in contrast to many centres throughout the world where its application would be considered the norm, almost irrespective of stage of presentation [890]. Such regimens usually make use of combinations of drugs, the detailed management of which is a matter for the specialist. The majority of regimens for non-small-cell lung cancer are based on cisplatin, the most active probably being mitomycin/vinblastine/cisplatin (MVP) and mitomycin/ifosfamide/cisplatin (MIC) [889]. Treatment of germ cell tumours is discussed in Chapter 49, lymphoma in Chapter 42 and small-cell lung cancer and non-small-cell lung cancer in Chapter 41.

This section deals with the individual properties of some of those cytotoxic drugs found to be most useful in respiratory medicine.

### *Cyclophosphamide*

Cyclophosphamide, like chlorambucil, is an alkylating agent of the nitrogen mustard type. Although mainly used as an antineoplastic drug, it is also useful as an immunosuppressive agent, being effective in autoimmune diseases where antibody is a major factor. Its principal uses in respiratory medicine include the treatment of small-cell lung cancer (see Chapter 41), Wegener's granulomatosis [891,892] (see Chapter 40) and Goodpasture's syndrome (see Chapter 38). It has also been used in a wide variety of other disorders, mainly in a supportive role with steroids, including cryptogenic fibrosing alveolitis (idiopathic pulmonary fibrosis) (see Chapter 31) [893,894]; other eosinophilic vasculitides, such as polyarteritis nodosa, Churg–Strauss syndrome and microscopic polyangiitis (see Chapter 40) [895–897]; rheumatoid vasculitis and Beçhet's syndrome (although clear-cut evidence of benefit is insubstantial) [898,899]; and pulmonary involvement

in a variety of collagen vascular disorders, such as polymyositis/dermatomyositis (see Chapter 53) [900]. Cyclophosphamide has been used in the past in the treatment of angioimmunoblastic lymphadenopathy (a type of T-cell lymphoma) [901] but the prognosis remains poor and it is not clear whether any real benefit accrues from its use. There is some evidence to suggest that pulse therapy with two 1-g doses of cyclophosphamide intravenously on consecutive days followed by three 1-g doses of methylprednisolone daily for 3 days might improve survival after moderate to severe paraquat poisoning [902,903].

#### *Mode of action*

The mode of action of cyclophosphamide is complex. An active hepatic metabolite, phosphoramidate mustard, alkylates or binds with many biologically important proteins and with DNA and RNA, so that the genetic processes of replication and transcription are impeded. Its antineoplastic activity is thought to arise from the formation of cross-linkages between strands of DNA and RNA and from the resulting inhibition of protein synthesis. Its immunosuppressive activity appears to be dose dependent and probably extends to both cell-mediated and humoral functions. Bone marrow suppression diminishes the numbers of circulatory neutrophils and the capacity of these and other cells to become involved in inflammatory immune processes is reduced. Antibody responses may also be reduced by the suppression of B lymphocytes, of which fewer are found in lymphoid follicles [904].

#### *Administration, distribution, metabolism and excretion*

Cyclophosphamide is well absorbed orally and may also be given intravenously. It is widely distributed and is converted in the liver to active metabolites including phosphoramidate mustard. Degradation also takes place in the liver and the drug is not recommended in patients with a plasma bilirubin greater than  $17\text{ }\mu\text{mol/L}$  ( $1.0\text{ mg/dL}$ ) or if the serum transaminase or alkaline phosphatase are more than twice the upper limit of normal. The plasma half-life of the parent drug is about 6 h. As excretion is renal (about one-quarter as unchanged drug and the remainder in the form of metabolites) the plasma half-life is prolonged in renal insufficiency and cyclophosphamide is not recommended in patients with a plasma creatinine greater than  $120\text{ }\mu\text{mol/L}$  ( $1.5\text{ mg/dL}$ ).

#### *Dosage*

Dosage varies according to clinical circumstances and usually depends on the combination chemotherapy protocol followed. An antineoplastic oral dose is usually  $2\text{--}6\text{ mg/kg}$  daily in divided doses depending on the composition of the combination chemotherapy regimen, whereas the dose for immunosuppression might be  $1\text{--}2\text{ mg/kg}$

daily. When the drug is used intravenously in neoplastic disease, a low-dose regimen might use  $2\text{--}6\text{ mg/kg}$  as a single dose weekly, a medium-dose regimen  $10\text{--}15\text{ mg/kg}$  similarly and a higher-dose regimen  $10\text{--}40\text{ mg/kg}$  as a single dose at  $10\text{--}20$  day intervals. When cyclophosphamide therapy is initiated at relatively high doses, the white cell count should be checked on alternate days, the aim being to prevent it from falling below  $3\times 10^9/\text{L}$ . Once a more stable maintenance dose has been achieved, white cell counts may be made weekly and then every 2 or 3 weeks, so long as treatment is continued.

#### *Adverse effects and precautions*

Cyclophosphamide, in common with other cytotoxic drugs, may produce many side-effects [905,906]. Nausea and vomiting occur commonly with higher doses and are treated symptomatically with agents such as prochlorperazine, domperidone or a specific 5-hydroxytryptamine ( $5\text{-HT}_3$ ) antagonist such as ondansetron, these proving very effective antiemetic drugs in cancer chemotherapy [907]. Mucosal ulceration may occur.

Myelosuppression is unavoidable and indeed the white cell count is commonly used to gauge the effectiveness of treatment and as a means of regulating the dose. Once the white count begins to fall in response to treatment, it may continue to do so for 7–14 days and recovery may take about 3 weeks. The reduced white cell count increases the risk of infection, which may be minimized by avoiding reductions in the neutrophil count to below  $1\times 10^9/\text{L}$  and in the total white cell count to below  $3\times 10^9/\text{L}$ . One way to achieve this is to temporarily withhold cyclophosphamide if the total white cell count drops below  $4\times 10^9/\text{L}$  (or if the platelet count dips below  $100\times 10^9/\text{L}$ ). Patients should be warned of the risk of infection and to report such symptoms promptly, as well as bleeding or bruising should these occur. It is now possible to treat severe neutropenia with parenteral recombinant human granulocyte colony-stimulating factor, thereby reducing the incidence of associated sepsis, although there is as yet no evidence that it improves overall survival.

Alopecia is inevitable following high-dose treatment and may develop over about 3 weeks. Hair usually regrows if the drug is stopped. This problem is diminished at lower doses and may not occur on maintenance therapy of  $2\text{ mg/kg}$  daily, although this cannot be guaranteed.

Chemical cystitis may occur with high-dose treatment or following long-term low-dose therapy. It is caused by a metabolite of cyclophosphamide called acrolein, which is toxic to the epithelium of the urinary tract. This cystitis may be haemorrhagic, particularly following high doses, and may result in bladder contracture and fibrosis or even fatality if the drug is not stopped. When high-dose therapy is necessary it is essential to keep the patient well hydrated in order to reduce the likelihood of this complication. Mesna, which reacts specifically with acrolein, may

be given parenterally initially and subsequently orally as a prophylactic against urothelial toxicity when cyclophosphamide is used at high dosage (>2 g intravenously) or in those patients with a previous history of urothelial toxicity from cyclophosphamide. Cystitis complicating cyclophosphamide therapy usually resolves within a few days of drug withdrawal.

Pulmonary fibrosis may occur during treatment with cyclophosphamide as with other cytotoxic agents and also with radiotherapy so that it may be difficult to apportion blame. This adverse effect is probably related to the cumulative dose and may occur after the drug has been discontinued [908]. Treatment with steroids has been advocated but no convincing evidence of benefit exists.

It is recognized that cytotoxic drugs may themselves have a carcinogenic effect. Leukaemia, usually acute, and lymphomas may occur with greater than expected frequency for several years following the administration of cyclophosphamide, as may urinary tract neoplasms, usually carcinoma of the bladder [909,910]. Such complications are generally a feature of long-term chemotherapy. Meta-analysis of early non-small-cell lung cancer trials that made use of long-term oral alkylating agents such as cyclophosphamide in single-drug form showed a survival disadvantage [911].

As with all cytotoxic therapy, the drug should only be used in pregnancy after very careful consideration of the considerable risks to the fetus versus benefit to the patient; adequate contraceptive precautions should be taken if either partner is taking the drug. The use of cyclophosphamide in younger patients is associated with infertility that is usually reversible.

### *Ifosfamide*

Ifosfamide is an alkylating agent of the nitrogen mustard type, related to cyclophosphamide but with a different and larger spectrum of activity and a different toxicity profile. It is used as an antineoplastic drug and has activity in non-small-cell lung cancer, for which its parent drug cyclophosphamide is relatively ineffective. In this role it is generally given as combination chemotherapy with cisplatin and another agent, for example mitomycin/ifosfamide/cisplatin.

#### *Mode of action*

This is similar to cyclophosphamide. Ifosfamide interacts with DNA, cross-linking resulting in inhibition of protein synthesis.

#### *Administration, distribution, metabolism and excretion*

Ifosfamide is formulated for intravenous administration. It is highly lipid soluble and widely distributed. It is made up as an 8% solution for infusion or as a more dilute solu-

tion for bolus injection. Ifosfamide is a prodrug that has no cytotoxic activity until activated in the liver by microsomal enzymes, so that local tissue damage is unlikely if the drug extravasates. The drug is primarily excreted as its metabolites via the kidneys.

#### *Dosage*

Dosage varies according to clinical circumstances and usually depends on the combination chemotherapy protocol followed. Doses of 5 g/m<sup>2</sup> over 24 h every 21 days or 1.5 g/m<sup>2</sup> as single daily doses for 5 days repeated every 21 days have been used as single agents in small-cell lung cancer.

#### *Adverse effects and precautions*

These are similar to cyclophosphamide. Chemical cystitis is the main dose-limiting adverse effect and is caused by the metabolite acrolein, which is toxic to the epithelium of the urinary tract. This cystitis may be haemorrhagic, particularly following high doses, and may result in bladder contracture and fibrosis. When high-dose therapy is necessary it is essential to keep the patient well hydrated in order to reduce the likelihood of this complication. Mesna, which reacts specifically with acrolein, is given routinely with ifosfamide, preferably orally. Cystitis usually resolves within a few days of drug withdrawal.

Myelosuppression occurs, although to a lesser extent than with its parent alkylating agent cyclophosphamide, the white cell count usually reaching a nadir 5–10 days after commencement of therapy and recovering within 3 weeks. Patients should be warned of the risk of infection and to report such symptoms promptly, as well as bleeding or bruising should these occur. Infrequent encephalopathic symptoms have been described, in which circumstance the drug must be stopped. Ifosfamide is contraindicated if the serum creatinine is greater than 120 µmol/L (1.5 mg/dL), if the bilirubin is greater than 17 µmol/L (1 mg/dL) or if the transaminases or alkaline phosphatase are greater than 2.5 times the upper limit of normal. As with all cytotoxic therapy, the drug should only be used in pregnancy after very careful consideration of the considerable risks to the fetus versus benefit to the patient; adequate contraceptive precautions should be taken if either partner is taking the drug.

### *Azathioprine*

Azathioprine, a cytotoxic immunosuppressant, is a purine analogue with similar actions to 6-mercaptopurine, to which it is metabolized. It has been used largely to treat diseases whose pathogenesis is thought to involve disordered immune function. Although it may be used alone, it is more usual for it to be used in conjunction with systemic corticosteroids such as prednisolone. It complements

cyclosporin in immunosuppressive therapy following solid organ transplantation. Reports of its efficacy are often based on retrospective data and individual case reports rather than on controlled prospective studies. It has been used in Wegener's granulomatosis, usually when cyclophosphamide has had to be discontinued because of unacceptable side-effects such as haemorrhagic cystitis [891,912]. It has also been used to treat other vasculitides [897], such as Churg–Strauss syndrome if a response to corticosteroids has not been achieved [913], and cryptogenic fibrosing alveolitis (idiopathic pulmonary fibrosis) in similar circumstances [893,914]. Azathioprine may also be used with steroids, either in a supporting role (when response to steroids is inadequate) or commonly in a steroid-sparing role (when the steroid dose required for control is unacceptably high) for the treatment of cryptogenic fibrosing alveolitis [914] and sometimes in those forms of fibrosing alveolitis associated with rheumatoid disease, systemic lupus erythematosus, dermatomyositis and polymyositis [915,916] (see Chapter 53). The drug has also been used to support steroids in the treatment of idiopathic pulmonary haemosiderosis [917,918] (see Chapter 51).

#### *Mode of action*

The mechanisms by which azathioprine acts as an immunosuppressant are poorly understood. It is recognized that the drug is a purine antagonist and its effects on intracellular metabolism may result in the inhibition of nucleic acid synthesis, preventing the proliferation of cells involved in the immune response. Its activities include the suppression of bone marrow, with depletion of circulating polymorphs and monocytes and diminution of the numbers of macrophages in the lungs and other tissues. At therapeutic dosage, T- and B-lymphocyte function and antibody production are impaired, and one of its more important clinical uses, as an immunosuppressant in transplant recipients, results from its ability to inhibit the recognition of transplanted material by the suppression of antibody responses due to immunologically competent lymphoid cells.

#### *Administration, metabolism and excretion*

Azathioprine is well absorbed from the gastrointestinal tract after oral administration, following which it is metabolized to its active form, 6-mercaptopurine. This enters cells and undergoes conversion into the active moieties, which are purine thioanalogues. Further metabolism is largely hepatic and is mediated by xanthine oxidase (see below). Excretion, chiefly of metabolites, is mainly renal and dosage reduction may be necessary in renal insufficiency. An intravenous preparation is also available but the oral route is preferred.

#### *Dosage*

The usual maintenance dose range in respiratory disease is 1–3 mg/kg daily orally, although even smaller doses occasionally suffice. A therapeutic response may take 2 weeks to 1 month to become evident. The blood count, including platelets, should be monitored at least weekly for the first 2 months or more frequently if high doses are used and thereafter monthly or at least every 3 months. The dose may be titrated against the white cell count and the treatment stopped if this falls below  $3 \times 10^9/L$  until sufficient recovery has occurred. For immunosuppression following organ transplantation an induction dose of 5 mg/kg orally or intravenously may be given on the first day, followed by a maintenance dose of 1–4 mg/kg daily orally or according to the protocol adopted. Cyclosporin (see below) is a usual co-immunosuppressant but if the use of this is limited by renal insufficiency, the addition of prednisolone (0.2 mg/kg daily) to azathioprine may be required. Doses of azathioprine at the lower end of the recommended ranges are advised if the drug has to be used in the presence of renal or hepatic insufficiency.

Allopurinol, a xanthine oxidase inhibitor, blocks the hepatic degradation of the active metabolite of azathioprine (6-mercaptopurine) so that toxicity is likely if these two drugs are used together, unless the dose of azathioprine is reduced. Such combined use is best avoided if possible.

#### *Adverse effects and precautions*

As with all cytotoxic drugs, its use is limited by toxic side-effects. The most important of these is myelosuppression so that careful monitoring of peripheral blood counts is necessary. For general purposes these are recommended at least weekly for the first 8 weeks then monthly or at least every 3 months thereafter. All cell series may be depressed, but leucopenia and thrombocytopenia occur more commonly and are dose limiting. A few patients have a rare enzymatic deficiency that predisposes them to myelosuppression by azathioprine. Occasionally, megaloblastic erythropoiesis and macrocytosis may occur [919].

Secondary infection, often with opportunistic organisms, may occur as a result of immunosuppression (see Chapter 52), especially if the white cell count is allowed to fall too far. Patients should be warned of the risk of infection and asked to report such symptoms promptly, as well as bleeding or bruising should these occur. Gastrointestinal side-effects include mucosal ulceration, nausea, vomiting and diarrhoea. Such adverse effects may be avoided to some extent by taking the drug with food in divided doses, but sometimes temporary dose reductions or cessation of therapy are required. More seriously, azathioprine may cause hepatotoxicity in an apparently idiosyncratic manner, liver function tests showing both

hepatic and cholestatic features [920]. This may necessitate withdrawal of the drug but is usually reversible. Pancreatitis may also occur but is rare. Idiosyncratic hypersensitivity reactions may occur with azathioprine [921] and become manifest with one or more of the following: fever, rigors, erythematous rash, myalgia, arthralgia, malaise, nausea, vomiting, diarrhoea, dizziness and hypotension. Azathioprine should be stopped in this context, following which recovery is the rule.

As with other cytotoxic drugs, interstitial pneumonitis that may result in pulmonary fibrosis has been described but is rare [922]. Diffuse bilateral pulmonary infiltration may occur and it may be necessary to exclude opportunistic infection. Recovery of impaired lung function following discontinuance of the drug cannot be guaranteed. There are a number of reports of neoplastic disease occurring in patients following treatment with azathioprine and other antineoplastic or immunosuppressive drugs [923]. As with all cytotoxic therapy, the drug should only be used in pregnancy after very careful consideration of risks versus benefit and adequate contraceptive precautions should be taken if either partner is taking the drug.

### *Cyclosporin*

Cyclosporin (ciclosporin) is a potent immunosuppressant cyclic peptide metabolite that revolutionized the field of organ transplantation [924]. It is extracted from the fungus *Tolypocadium inflatum* and although used chiefly in solid organ and bone marrow transplant work, to prevent and treat allograft rejection, it is also used in the short-term treatment of severe atopic eczema that has become resistant to conventional therapy and for various other inflammatory/immune dermatological, rheumatological and renal indications [925]. It has been the subject of small experimental trials in a variety of other inflammatory or autoimmune disorders involving the lungs, including severe steroid-dependent asthma [926], cryptogenic fibrosing alveolitis [927] and sarcoidosis [928,929]. It has virtually no myelotoxicity but its main dose-limiting adverse effects are related to severe nephrotoxicity and it has a very low toxic–therapeutic ratio.

### *Mode of action*

The precise mechanism of its action is unknown, although it is thought to interfere with the synthesis of lymphokines with resultant inhibitory effects on the activation of T lymphocytes [924]. It does not depress haematopoiesis, nor does it affect the function of phagocytic cells.

### *Administration, metabolism and excretion*

Bioavailability differs between individual oral formulations of cyclosporin so that care should be taken in pre-

scribing and dispensing the same preparation. Before the availability of a microemulsion formulation, the absorption of cyclosporin from the gut exhibited wide interpatient variation. It is fat soluble and highly bound to lipoproteins and erythrocytes. There are several separate hepatic metabolic pathways and the principal route of excretion is biliary, with little urinary excretion so that renal impairment does not alter its elimination. The terminal half-life is about 6 h in healthy subjects, increasing to about 20 h in severe liver disease.

### *Drug interactions*

Many drugs interact with cyclosporin, so that where there is any doubt a formulary or the manufacturer's summary of product characteristics should be consulted. Some drugs, such as macrolide antibiotics, reduce cyclosporin metabolism and therefore increase the risk of toxicity, as do some calcium channel blockers, including nifedipine and diltiazem, and some azole antifungal drugs, including ketoconazole and itraconazole. On the other hand, liver enzyme-inducing drugs increase its metabolism, lowering blood levels and therefore increasing the risk of rejection or failure of treatment. These include phenytoin, carbamazepine, phenobarbital and rifampicin. Drugs that are themselves potentially nephrotoxic may increase the nephrotoxicity of cyclosporin, examples being NSAIDs (which also increase the risk of hepatotoxicity), aminoglycosides, ciprofloxacin and amphotericin. Clinical gout and hyperuricaemia are problematical because of the potential nephrotoxicity of NSAIDs and because colchicine may increase cyclosporin levels as may allopurinol, so that blood level measurements and dose adjustment may become necessary. Angiotensin-converting enzyme inhibitors and potassium-sparing diuretics both increase the risk of hyperkalaemia and the diet should not be high in potassium. The risks of rhabdomyolysis may be increased if hypercholesterolaemia is treated with certain HMG-CoA reductase inhibitors. Nifedipine may increase the risk of gingival hypertrophy. Grapefruit or grapefruit juice should be avoided for 1 h before the dose as it increases plasma cyclosporin concentration.

### *Dosage*

For induction of immunosuppression in solid organ transplantation 10–15 mg/kg may be given orally preoperatively in two divided doses, followed by 10–15 mg/kg daily for the first week or two postoperatively, also as two divided doses, thereafter adjusting down to a maintenance dose of 2–6 mg/kg daily as two divided doses. Cyclosporin may be given as an intravenous infusion postoperatively until the patient can swallow, the relative bioavailability of oral to intravenous being 1:3. Doses of cyclosporin are reduced when other immunosuppressants

such as azathioprine or systemic steroids are used as well, many transplant centres using combined regimens with the object of keeping the dose of cyclosporin low in order to reduce the likelihood of renal damage. Dosages of cyclosporin are adjusted by monitoring renal function and by assaying cyclosporin trough levels in whole blood (taken just before a due dose) to be sure that they fall within the therapeutic range [930]. Different assay techniques are available and each laboratory should establish its own therapeutic and toxic concentration ranges, based on local practice. These levels have to be measured frequently in the early post-transplant stage. Lower trough levels of cyclosporin may be accepted after the first 6 months of therapy without increased risk of rejection. The serum creatinine and urea have to be measured very frequently in the first month after transplantation, then every week or two for the first year and thereafter monthly, depending on the stability of the situation.

For non-transplant situations, lower doses of cyclosporin that do not normally exceed 5 mg/kg daily are used.

#### *Adverse effects and precautions*

Many of the adverse effects are dose dependent so that the lowest possible dose should always be used. Renal function has to be monitored closely and dose adjustments made accordingly. Increases in the serum creatinine and urea in the first few weeks of treatment are generally dose dependent and reversible on dose reduction. Nephrotoxicity is minimal at doses of less than 2.5 mg/kg daily but higher doses or long-term administration may lead to structural changes in the kidneys, involving both vasculature and tubules, and may progress to interstitial fibrosis. Hypertension may also occur so that blood pressure should be monitored and appropriate hypotensive medication started if needed.

Other unwanted effects include nausea and vomiting and hepatotoxicity so doses may need reducing if liver enzymes or bilirubin climb. Occasional biochemical disturbances may occur, including hyperkalaemia, hyperuricaemia (sometimes with clinical gout, see above), hypercholesterolaemia (rhabdomyolysis may be more likely with HMG-CoA reductase inhibitors) and hypomagnesaemia. Patients may develop a rather hirsute appearance, with hypertrichosis, weight gain and oedema leading to problems with compliance. Gingival hypertrophy may occur. Myalgia, cramps, paraesthesiae and peripheral neuropathy are described, as are convulsions particularly in the presence of high blood levels of cyclosporin. As with any immunosuppressive therapy, patients are liable to develop opportunistic infections. There is an increased incidence of lymphoma (especially non-Hodgkin) and other malignancies, as seen with conventional immunosuppressants such as azathioprine. The

prescriber needs to be on guard against the possibility of drug interactions (see above).

#### *Chlorambucil*

Chlorambucil is an antineoplastic and immunosuppressive agent derived from mustard and belongs to the nitrogen mustard group of alkylating agents (like cyclophosphamide). It has been used mainly in the treatment of Hodgkin's disease, non-Hodgkin lymphomas, chronic lymphocytic leukaemia and Waldenström's macroglobulinaemia. It is occasionally used as an immunosuppressant although, as it is toxic, usually only when the patient is unresponsive to steroids or intolerant of them.

Like cyclophosphamide and azathioprine, it has been used in steroid-resistant Churg–Strauss syndrome [931]. It has been used to treat vasculitides such as Wegener's granulomatosis but has been superseded by cyclophosphamide or azathioprine. Another use of chlorambucil is as an alternative to cyclophosphamide and azathioprine in certain collagen vascular conditions, such as mixed connective tissue disease which combines the clinical features of scleroderma, systemic lupus erythematosus and polymyositis [932].

#### *Mode of action*

Active metabolites of chlorambucil alkylate or bind to many intracellular structures including nucleic acids. Cross-links are established between DNA and RNA so that DNA replication and RNA transcription are impeded. The mechanism by which immunosuppression occurs is unclear but it is likely to be related, at least in part, to the suppressive effect of the drug on bone marrow activity.

#### *Administration, metabolism and dosage*

Chlorambucil is taken orally and is well absorbed from the gastrointestinal tract. Metabolism is hepatic, the major metabolite being phenylacetic acid mustard. Excretion is renal but less than 1% of a dose appears in the urine other than as metabolites.

The usual dose when used as an immunosuppressant is 100–200 µg/kg as a single daily dose. The blood count, including platelets, should be checked at least weekly at first, aiming to keep the white cell count above  $3 \times 10^9/L$  and the platelet count above  $100 \times 10^9/L$  [932].

#### *Adverse effects*

As with other cytotoxic drugs, the most important side-effect is myelosuppression. Depression of all cell lines may occur, the white cell count being particularly affected. After a single high dose of chlorambucil, the white cell and

platelet counts reach a trough at 7–10 days and recovery may take 2–3 weeks. Similarly, when the drug is being taken on a daily basis, the count may continue to fall for some days after the last dose. Very high doses may cause irreversible marrow suppression. Resultant immunosuppression, particularly in the presence of neutropenia, may lead to opportunistic secondary infection.

Less serious but nevertheless distressing gastrointestinal symptoms may occur, including mucosal ulceration, nausea, vomiting and diarrhoea. As with other immunosuppressants, chlorambucil may cause chromosomal damage and carries the risk of secondary neoplastic complications, particularly leukaemia [933,934]. This may be related to the duration of therapy. Interstitial pneumonitis can occur and may lead to pulmonary fibrosis [935,936]. This adverse effect may be dose related and response to discontinuance of the drug and corticosteroid therapy is uncertain but has been reported. Infertility due to azoospermia or amenorrhoea can occur, as is the case with cyclophosphamide. All cytotoxic drugs must be considered to be potentially teratogenic, carrying the risk of fetal damage. Other rare side-effects include aseptic cystitis, neurotoxicity including peripheral neuropathy and seizures, hepatotoxicity, and widespread rashes progressing to Stevens–Johnson syndrome.

### *Doxorubicin*

Doxorubicin (often denoted by 'A' for Adriamycin in multidrug mnemonics) is a cytotoxic anthracycline antibiotic, being produced by a species of *Streptomyces*. It is used widely in combination chemotherapy for the treatment of various malignancies, including acute leukaemias, lymphomas and small-cell lung cancer. Small-cell lung cancer may be treated with a variety of regimens some of which contain doxorubicin, for example cyclophosphamide/doxorubicin/vincristine ('CAV' see below). A liposomal formulation of doxorubicin for intravenous use has been licensed for treating Kaposi's sarcoma in patients with AIDS.

The mode of action of doxorubicin, while not fully understood, seems to involve its concentration in cell nuclei where it binds to and disrupts the structure of DNA. It also forms free-radicals and may have direct effects on the integrity of lipid membranes, these actions possibly accounting for its toxic and dose-limiting effects on normal cells.

### *Administration, metabolism, excretion and dosage*

The drug is given as a bolus over 2–3 min, being injected into the tubing of a freely running intravenous infusion. Doxorubicin is rapidly metabolized by the liver to produce an active substance, adriamycinol. Over 70% of excretion is biliary, either as unchanged doxorubicin or as

adriamycinol. Less than 10% of excretion is renal; nevertheless such excretion may colour the urine red for up to 48 h, a phenomenon about which the patient should be forewarned. Liver disease increases the likelihood of toxicity and if the agent has to be given in the presence of hepatic dysfunction, the dosage should be reduced.

Dosage is conventionally calculated according to body surface area, a usual dose being 60–75 mg/m<sup>2</sup> every 3 weeks. However, when used in combination chemotherapy the dose may need to be reduced to 30–40 mg/m<sup>2</sup>, for example cyclophosphamide 600 mg/m<sup>2</sup>, doxorubicin 40 mg/m<sup>2</sup> and vincristine 1 mg/m<sup>2</sup> to a maximum 2 mg repeated every 21 days for a maximum of six cycles in 'CAV' which is commonly used in the treatment of small-cell lung cancer. The total dose should be limited to about 400 mg/m<sup>2</sup> in order to reduce the chance of cardiotoxicity [937].

### *Adverse effects*

Adverse effects include myelosuppression, the white count reaching its nadir about 10–14 days after a dose and taking up to 3 weeks to recover. Doxorubicin is particularly noted for its potential toxicity to heart muscle and its propensity to cause serious tissue necrosis should it be allowed to extravasate from an intravenous injection site. Cardiotoxicity is a dose-related side-effect. Acute effects include the production of various cardiac dysrhythmias or rarely myocarditis. Cumulative cardiotoxicity is much more common and produces a cardiomyopathy, ultimately resulting in myocardial fibrosis that may precipitate heart failure [937]. Its use should therefore be avoided in patients with pre-existing heart disease. Heart failure due to cardiomyopathy may occur without warning several weeks after discontinuation of therapy. These effects are more likely to become clinically significant if mediastinal radiation has been given, the patient has pre-existing coronary artery or hypertensive heart disease, or alkylating agents (e.g. cyclophosphamide, ifosfamide, chlorambucil or lomustine) are used concurrently. Cardiotoxicity may be limited by using a 'dosage ceiling' (see above). A reduction in the height of the QRS complex on the ECG is said to be indicative of toxicity and a relative contraindication to continued treatment with this agent.

Tissue necrosis may occur with other cytotoxic agents such as cyclophosphamide, but is particularly severe if doxorubicin finds its way into extravascular tissues. The extent to which tissue is damaged is probably a consequence of the high degree to which the drug is bound [938]. Such accidents should be guarded against with extreme care by ensuring that the injection is given by fast-running infusion into a clearly patent intravenous line.

Other side-effects include buccal ulceration, nausea and vomiting, diarrhoea and alopecia (which is virtually

inevitable, although hair may regrow when treatment ceases). Radiotherapy following doxorubicin may produce an intense radiation pneumonitis, with strikingly demarcated borders marking the edge of the radiation field.

### **Mitomycin**

Mitomycin is another cytotoxic antibiotic used in combination chemotherapy in the treatment of a variety of solid tumours, including breast and upper gastrointestinal tract cancers. It is also under investigation in the management of advanced non-small-cell lung cancer in combinations such as mitomycin/ifosfamide/cisplatin (MIC) and mitomycin/vinblastine/cisplatin (MVP) [939,940]. Mitomycin becomes activated in tissues, forming an alkylating agent that both disrupts and interferes with the synthesis of DNA.

#### *Administration, metabolism, excretion and dosage*

Mitomycin is given by intravenous infusion and must be administered with great care in order to avoid extravasation (see p. 289). The chief site of metabolism is the liver and about 10% is excreted unchanged in the urine. Doses of 6–10 mg/m<sup>2</sup> may be used in 4-weekly combination chemotherapy schedules for non-small-cell lung cancer. Failure to respond within two cycles of treatment would be reason for abandonment of such a course.

#### *Adverse effects*

The principal side-effect is myelotoxicity. The nadir tends to be later than with other drugs used for treating cancer, occurring at about 4 weeks. Myelotoxicity with this drug tends to be cumulative with repeated courses, the platelets and white cells being particularly affected. The drug should not be repeated before the white cell count has recovered to  $3 \times 10^9$ /L and the platelets to  $90 \times 10^9$ /L. The drug is also nephrotoxic so that renal function should be monitored. Pulmonary toxicity is a rare but well-described side-effect of mitomycin. Although it may reverse with corticosteroids, progressive lung fibrosis may occur [941]. Nausea and vomiting may occur. Extravascular leakage may cause tissue necrosis.

### **Vinca alkaloids (vincristine, vinblastine, vindesine, vinorelbine)**

Vincristine, vinblastine and vindesine are antineoplastic agents derived from the periwinkle plant. Vinorelbine is a more recent semisynthetic vinca alkaloid. They are very similar in their properties and structure, differing mainly with respect to their principal dose-limiting side-effects, that of vincristine being peripheral neuropathy and that of vinblastine, vindesine and vinorelbine being myelosup-

pression. Vinorelbine may cause both these side-effects but, like vinblastine, its dose is mainly limited by myelosuppression. They are used in combination with other oncolytic drugs to treat a wide variety of malignancies, including leukaemias, lymphomas and various solid tumours. Vincristine is included in many combination chemotherapy regimens used for treating small-cell lung cancer, for example cyclophosphamide/doxorubicin/vincristine (CAV). The use of vinblastine and vinorelbine continues to be investigated as part of platinum-based combination chemotherapy in the management of inoperable non-small-cell lung cancer. The mode of action of these drugs appears to involve their attachment to intracellular proteins such as tubulin that are concerned with the facilitation of microtubule formation in the mitotic spindle of the dividing cell.

#### *Administration, metabolism, excretion and dosage*

Vinca alkaloids are administered as slow intravenous boluses or short infusions, care being taken not to allow extravasation (see p. 289). Metabolism occurs in the liver and up to 90% of a dose is excreted in bile, mainly in the form of breakdown products. Reduction in dosage is necessary in hepatic but not renal insufficiency. A vinca alkaloid is often included as one component of a 3-weekly cycle of combination chemotherapy in lung cancer. Vincristine is included in many combination chemotherapy regimens used for treating small-cell lung cancer, for example cyclophosphamide 600 mg/m<sup>2</sup>, doxorubicin 40 mg/m<sup>2</sup> and vincristine 1 mg/m<sup>2</sup> to a maximum 2 mg repeated every 21 days for a maximum of six cycles. Vinblastine, vindesine and vinorelbine may be included in platinum-based regimens (see cisplatin), such as mitomycin/vinblastine/cisplatin, vindesine/cisplatin and vinorelbine/cisplatin, currently under investigation in the management of non-small-cell lung cancer.

A usual dose of vincristine in small-cell lung cancer is 1.4 mg/m<sup>2</sup> (up to a usual maximum dose of 2 mg in adults), which is reduced or stopped in the presence of a significant neurological deficit (see below). The dose of vinblastine may be increased incrementally from 3.7 mg/m<sup>2</sup>, according to the white cell count. Vindesine has been used in combination chemotherapy at weekly doses of 2.5 mg/m<sup>2</sup> and vinorelbine at 30 mg/m<sup>2</sup>. Dosing is regulated according to the white cell and platelet counts, which have to be monitored closely. An oral formulation of vinorelbine is under investigation.

#### *Adverse effects*

The most important side-effect of vincristine is peripheral neuropathy [942], neurotoxicity being uncommon with vinblastine. Impaired neuronal function may result from both demyelination and axonal degeneration; mild neuro-

toxicity is to be expected with therapeutic doses of vincristine. Early symptoms, which include paraesthesiae and peripheral sensory loss, are common as is the loss of previously present tendon reflexes at the ankles. Further treatment may lead to difficulties with fine movements of the fingers and wrist and foot drop, with resultant disturbances of gait. More serious paresis may occur in severe cases. Autonomic neuropathy may also occur and may cause constipation, intestinal ileus and urinary retention. Cranial nerve palsies have been described but are rare. Neurotoxicity is dose dependent and occurs more readily in the elderly. It is usual practice to reduce the dose of vincristine by half with early neurological symptoms and signs (unusual before 4–6 mg) and to stop it altogether if the problem progresses or if significant weakness or ileus develops (unusual before 10–12 mg) [943]. Functional recovery is usual if the drug is stopped at an early stage but recovery from more serious deficits may be both delayed and incomplete.

Myelosuppression is the major dose-limiting effect of vinblastine, vindesine and vinorelbine, with which neurotoxicity is unusual. The neutrophils are principally affected and reach a trough up to 10 days after a dose, recovery occurring within 3 weeks.

Other adverse effects are shared and include severe tissue necrosis if the drug is allowed to extravasate during an intravenous infusion. The same precautions should be followed as for doxorubicin (see p. 289). Nausea, buccal mucosal ulceration, rashes and reversible alopecia may occur. Cardiotoxicity, lung fibrosis and inappropriate ADH secretion are also recorded but are rare [944].

### *Lomustine*

Lomustine is an antineoplastic alkylating agent of the nitrosourea type that has been used in combination chemotherapy to treat small-cell lung cancer and other usually solid tumours. It is taken orally. Lomustine and its metabolic products appear to act, in broad terms, by causing the inhibition of nucleic acid function and more specifically of DNA synthesis.

#### *Administration, distribution, metabolism and dosage*

Lomustine is well absorbed orally. It is lipid soluble and its active metabolites cross the blood–brain barrier and penetrate the CNS, enabling the drug to be used in the treatment of brain tumours. It is rapidly metabolized by the liver and primarily excreted as metabolites by the kidneys [945].

The usual dose range is 100–130 mg/m<sup>2</sup> given as a single dose no more frequently than every 6–8 weeks. The dose should not be repeated until the white cell count recovers to  $4 \times 10^9$ /L and the platelet count to  $100 \times 10^9$ /L. Haematological toxicity may be cumulative, with increasingly low white cell and platelet counts following

repeated dosage. Lower doses may be used in combination chemotherapy and individual monographs should be consulted for further guidance.

#### *Adverse effects*

The major adverse effect is myelosuppression, which differs from that produced by other antineoplastic agents in that it is both delayed and sustained, so that white cell and platelet counts may not reach a trough until 4–6 weeks after the dose. This has important implications for dosage scheduling (see above). Nausea and vomiting are to be expected and usually begin within 4–6 h, taking a day or two to settle, although anorexia may last longer. Treatment is symptomatic with agents such as prochlorperazine, domperidone or a specific 5-HT<sub>3</sub> antagonist such as ondansetron. Unusual adverse effects include stomatitis, buccal ulceration, renal insufficiency, pulmonary fibrosis and alopecia.

### *Etoposide*

Etoposide is a semisynthetic antineoplastic derivative of podophyllotoxin, an active component of the naturally occurring substance podophyllin, long used topically in the treatment of warts and obtained from the root of the mandrake plant. It is one of the most active single agents in small-cell lung cancer but is usually given as part of a course of combination chemotherapy [946].

It is regarded as a 'broad-spectrum' cytotoxic agent and is also used to treat lymphomas, metastatic germ-cell tumours and acute leukaemias [947–949]. The use of etoposide as a single oral agent in patients with small-cell lung cancer with moderate or poor prognosis, in order to reduce the intensity of chemotherapy, has been found to produce inferior results to conventional intravenous combination chemotherapy [890,950]. The intracellular mode of action of etoposide is complex and poorly understood. It appears to inhibit DNA synthesis at the premitotic stage of cell division [951].

#### *Administration, metabolism, excretion and dosage*

Etoposide is usually given intravenously as part of 21-day cycles of combination chemotherapy but may be taken orally. The number of cycles is variable but six is often considered optimal, provided the patient is responding. The dose varies according to the myelosuppressive characteristics of the other drugs in the regimen but dosages of 80–120 mg/m<sup>2</sup> intravenously for three consecutive days are not uncommon, the agent being infused slowly over 30–60 min since more rapid administration may produce hypotensive reactions. The regimen may be repeated after 3 weeks if the white count is not less than  $4 \times 10^9$ /L and the platelet count not less than  $100 \times 10^9$ /L. Oral dosage

follows the same general pattern except that the doses are usually doubled because absorption is incomplete. Metabolism is hepatic, excretion being via the kidneys both in unchanged form and as metabolites.

#### *Adverse effects*

The principal dose-limiting adverse effect is myelosuppression, chiefly affecting the white cell and platelet counts, so that the drug is conventionally given on three to five consecutive days in 21-day cycles in order to allow the marrow to recover. The white cell count reaches a trough at about 2 weeks. More prolonged oral courses of etoposide in combination with cisplatin intravenously produce significant myelosuppression, with no advantage over conventional chemotherapeutic regimens in small-cell lung cancer. Nausea and vomiting occurs in about half of all patients treated and diarrhoea and buccal ulceration may also arise. Alopecia may also occur but is reversible. Other side-effects are rare and include wheezing and anaphylaxis.

#### *Cisplatin and carboplatin*

The discovery that compounds of platinum impaired cellular division was made serendipitously in the 1960s when a study looking into the effects of electrical fields on cellular growth reported that *E. coli* failed to divide in an apparatus when the current passed through platinum electrodes. This effect was found to be due to the production of *cis*-diamminedichloroplatinum or 'cisplatin' [952]. Cisplatin, and its later analogue carboplatin, are both platinum complexes that are thought to exert their cytotoxic effects by forming cross-linkages within and between DNA strands, as is the case with alkylating agents [953,954]. Both have been used in the combination chemotherapy of a variety of solid tumours, such as small-cell lung cancer and metastatic testicular, germ cell and ovarian cancers.

#### *Administration, metabolism, excretion and dosage*

Both cisplatin and carboplatin are given intravenously. Non-enzymatic conversion to inactive metabolites occurs and platinum is heavily bound by tissue and protein. Excretion is renal. One or other drug is usually given as part of a course of combination chemotherapy, being commonly combined with etoposide in the treatment of small-cell lung cancer (cisplatin/etoposide and carboplatin/etoposide). These compounds have also been included in trials of multidrug therapy in locally advanced non-small-cell lung cancer, for example mitomycin/vinblastine/cisplatin (MVP), mitomycin/ifosfamide/cisplatin (MIC), cyclophosphamide/doxorubicin/cis-

platin (CAP), or in combination with docetaxel, gemcitabine or vinorelbine, the general view being that platinum-based regimens are superior to other types of chemotherapy in advanced non-small-cell lung cancers [955]. Pre-dose estimations of creatinine clearance and blood urea are necessary before cisplatin administration, and the drug is best avoided if the serum creatinine is above  $100\mu\text{mol/L}$  ( $1.5\text{mg/dL}$ ), the blood urea higher than  $9\text{mmol/L}$  ( $55\text{mg/dL}$ ) or the creatinine clearance reduced by more than 25%. Even so, adequate hydration is recommended by priming the patient with 1–2 L of intravenous fluid in the 8–12 h before the dose of cisplatin in order to initiate a diuresis, and by giving the drug in a further 2 L of dextrose/saline over the next 6–8 h; 40 g mannitol may be added to this to maintain the diuresis. Concomitant use of other potentially nephrotoxic drugs is best avoided if possible. The drug is commonly given at a dose of  $50\text{mg/m}^2$  in multidrug regimens and is usually repeated after 3–4 weeks for about four cycles according to response. Leucopenia and thrombocytopenia may occur and the dose should not be repeated before the white cell count has recovered to  $4\times 10^9/\text{L}$  and the platelet count to  $100\times 10^9/\text{L}$ .

Heavy hydration is unnecessary with carboplatin but myelosuppression with leucopenia and thrombocytopenia should be expected, reaching a nadir by about 3 weeks, so that administration should not be repeated more than every 4 weeks. The dose ratio of carboplatin to cisplatin is about 4:1. Doses of  $300\text{mg/m}^2$  have been used in combination with etoposide. The dose has to be reduced in the presence of renal insufficiency.

#### *Adverse effects*

Cisplatin is potentially highly toxic [956], carboplatin being less so and therefore more manageable but more expensive. The principal dose-limiting side-effect of cisplatin is nephrotoxicity, resulting from renal tubular necrosis. This effect may be guarded against by avoiding cisplatin in patients with pre-existing renal insufficiency and by maintaining adequate hydration. Nausea and vomiting are to be expected and may be prevented by a rigorous antiemetic regimen using high-dose glucocorticoids (dexamethasone or methylprednisolone) and a  $5\text{-HT}_3$  antagonist (ondansetron or granisetron) or other agents [957,958]. Myelotoxicity occurs and requires regular blood count monitoring as with other agents. Neurotoxicity includes a dose-dependent sensory peripheral neuropathy, with paraesthesiae, numbness and impaired proprioception. Auditory loss with tinnitus may occasionally occur. The sensory peripheral neuropathy may progress after the drug has been stopped and recovery may be slow. Hypomagnesaemia may also arise.

Carboplatin causes less nausea and vomiting [959], and clinically significant nephrotoxicity and neurotoxicity appear to be uncommon [960], so that carboplatin may be useful in those who have renal insufficiency or who cannot tolerate the high fluid load required for cisplatin administration (see above). However, myelosuppression occurs more frequently with carboplatin, the platelets being particularly susceptible [960].

### *Methotrexate*

Methotrexate is classed as an antimetabolite, its mode of action being to competitively inhibit the enzyme dihydrofolate reductase. This prevents the formation of reduced folate, which is necessary in the synthesis of purines and pyrimidines and without which DNA synthesis is interrupted [961]. Methotrexate has been used as an antineoplastic agent in the treatment of leukaemias, non-Hodgkin lymphomas and various solid tumours including small-cell lung cancer. Its ability to interrupt the rapid turnover of cells is illustrated by its use in severe psoriasis. It also possesses some immunosuppressive properties that have led to its increasing use in refractory rheumatoid arthritis.

### *Administration, metabolism, excretion and dose*

Methotrexate may be administered intravenously or orally. Absorption following an oral dose is somewhat variable and in antineoplastic treatment intravenous administration is more usual. Intrathecal administration may be used in the treatment of leukaemia. Methotrexate may accumulate in ascitic or pleural fluid, which acts as a pool from which the drug may be subsequently released with enhancement of its toxicity. Its use in such situations is therefore best avoided altogether or followed, after an interval of 24 h, by four 6-hourly doses of oral calcium folinate 15 mg, which opposes its effect. Metabolism is both hepatic and intracellular. Excretion is primarily via the kidneys and renal insufficiency is a relative contraindication to its use as is severe hepatic impairment.

The dose for antineoplastic use is 15–50 mg/m<sup>2</sup> once or twice per week, or at a dose not exceeding 30 mg/m<sup>2</sup> daily for 5 days followed by a 'rest period' of at least 2 weeks in order to allow the bone marrow to recover. The dosage used will be influenced by the choice and dose of any other agents that may be used concurrently in combination chemotherapy.

### *Adverse effects*

The most notable side-effects of methotrexate are myelosuppression, particularly leucopenia and thrombocytopenia, and mucosal inflammation and ulceration

particularly affecting the gastrointestinal tract and resulting in painful buccal ulceration, severe diarrhoea and, in extreme cases, intestinal perforation. These and other serious side-effects can be treated with intravenous folinic acid (given as calcium folinate, see above), which antagonizes the effects of methotrexate. Less common side-effects include drug-related pneumonitis [962], which may appear with alarming rapidity, and pulmonary fibrosis, pleuritis and hepatic toxicity, all of which tend to occur with prolonged use, sometimes resulting in requests for assistance from worried rheumatological colleagues. Rashes, alopecia and infertility may also occur. High-dose therapy (used in experimental protocols) may cause renal tubular precipitation of drug products, and such rigorous treatment is invariably followed by 'folinic acid rescue' [961].

### *Gemcitabine*

Gemcitabine is an antimetabolite and is a fluorinated nucleoside analogue of cytarabine, having a broad spectrum of activity against a number of solid tumour types. It undergoes intracellular metabolism and its triphosphate metabolite is incorporated into DNA, replacing the natural nucleotide with resultant inhibition of DNA synthesis by a process known as chain termination. Gemcitabine is undergoing evaluation as single-drug therapy for patients with locally advanced (stage III) or metastatic (stage IV) non-small-cell lung cancer. There are some data to suggest that a 'partial response', defined as an apparent decrease in tumour size of at least 50%, may occur in 20% of patients but there is a lack of controlled trials to compare symptom control with this agent versus palliative radiotherapy and supportive care [963].

### *Administration, metabolism, excretion and dosage*

Gemcitabine has to be administered intravenously. The recommended dose for monotherapy in non-small-cell lung cancer is 1000 mg/m<sup>2</sup> given by infusion over 30 min once weekly for three consecutive weeks, followed by a 1-week rest period. This monthly cycle may then be repeated. It undergoes metabolism in various tissues including the liver and kidneys and its metabolites are excreted in the urine.

### *Adverse effects and precautions*

The drug is relatively well tolerated and can usually be administered in an outpatient setting. Nausea and vomiting may occur in a minority of patients but usually respond to standard antiemetics, such as prochlorperazine or metoclopramide, without a requirement for more potent 5-HT<sub>3</sub> antagonists. Blood counts should be

monitored every 2 weeks during treatment as myelosuppression may occur and is the predominant toxicity. It is as well to omit treatment or reduce the dose if the neutrophil count has reached  $1 \times 10^9/L$  or the platelet count  $100 \times 10^9/L$ . Biochemical abnormalities include mild elevations of hepatic transaminases, mild proteinuria and haematuria, although these urinary abnormalities are not usually associated with a rise in serum creatinine or urea. It is recommended that periodic checks of liver and renal function should be carried out. Macular rashes are not uncommon and need not lead to discontinuation of the drug. Patients may experience mild self-limiting influenzal-type symptoms during treatment. Dependent oedema may also occur. Hair loss is uncommon. The use of gemcitabine should not be combined with radical radiotherapy as severe radiation-induced pneumonitis and oesophagitis may complicate this intervention.

#### *Taxanes: paclitaxel and docetaxel*

The taxanes are a relatively new group comprising paclitaxel, extracted from the bark of the Pacific yew (*Taxus brevifolia*), and docetaxel from the needles of the common European yew (*Taxus baccata*), long known to have poisonous leaves, seeds and bark, its destructive properties also being of historical interest as the source of the longbow staves of medieval archers. Both compounds interrupt microtubule formation in the mitotic spindle of the dividing cell by promoting the polymerization of the intracellular protein tubulin. Both drugs have clinical activity against a broad spectrum of solid tumours, including non-small-cell lung cancer, breast and ovarian cancer. Paclitaxel currently has a UK licence permitting its use in non-small cell lung cancer.

#### *Administration, metabolism, excretion and dosage*

Paclitaxel is given by slow intravenous infusion following premedication (see below). The optimal rate of infusion (1, 3 or 24 h) has been the subject of study and debate. Paclitaxel and docetaxel undergo hepatic metabolism by cytochrome P450 enzymes, so that care should be taken to avoid interactions. Although they are excreted predominantly in the bile, nevertheless dose modifications are recommended in renal insufficiency and the drugs are better not given if the bilirubin level is raised and the dose reduced in the presence of moderately raised transaminases. Conventional doses of paclitaxel in non-small-cell lung cancer trials are usually  $135\text{--}225\text{ mg/m}^2$  and the drug has been combined with other agents such as carboplatin and cisplatin in 3-weekly cycles [964]. Docetaxol is usually given at a dose of  $100\text{ mg/m}^2$  by intravenous infusion over 1 h every 3 weeks. This compound too is the subject of ongoing comparative trials with cisplatin and non-

platinum-based drugs in advanced non-small-cell lung cancer [965].

#### *Adverse effects and precautions*

Neutropenia is the principal dose-limiting side-effect of both paclitaxel and docetaxel. With paclitaxel it usually occurs in the second week after treatment, the marrow recovering by the end of the third. Hypersensitivity reactions are also problematical and have to be guarded against [966]. Hypersensitivity reactions occurred in over one-quarter of patients in early trials of paclitaxel and may have been caused by a castor oil-based vehicle. These included urticarial rashes, wheezing and hypotension within a few minutes of dosing, so that premedication with a corticosteroid (e.g. dexamethasone 20 mg orally 6–12 h before), an antihistamine (e.g. chlorphenamine [chlorpheniramine] 10 mg i.v. 30–60 min before) and an  $H_2$  antagonist (e.g. cimetidine 300 mg i.v. 30–60 min before) is necessary, this protocol having substantially reduced the incidence of major hypersensitivity reactions. Electrocardiographic abnormalities may include sinus bradycardia, conduction defects and dysrhythmias that are seldom symptomatic. Mucocytosis may also occur with high doses. A predominantly sensory peripheral neuropathy with 'stocking and glove' numbness and paraesthesiae may occur with multiple courses at conventional dose levels (cf. vincristine, cisplatin) and is a major toxicity in paclitaxel/cisplatin regimens, a problem that may be reduced by the substitution of carboplatin. Transient myalgia and scintillating scotomas have also been reported.

Docetaxel may also cause hypersensitivity reactions and peripheral neuropathy. In addition, it may cause fluid retention with troublesome dependent oedema. It is recommended that a 5-day course of dexamethasone, 8 mg twice daily starting the day before docetaxel, is given to avoid hypersensitivity and fluid retention problems. Both drugs may cause nausea, vomiting and reversible alopecia.

#### *Procarbazine*

Procarbazine is an antineoplastic alkylating agent and mild monoamine oxidase inhibitor. It is a standard agent in the multidrug treatment of Hodgkin's disease, for example mustine/vincristine/procarbazine/prednisolone (MOPP). The precise mode of action is unknown but it is thought to inhibit the synthesis of RNA, DNA and other cellular protein constituents.

#### *Administration, metabolism, excretion and dosage*

Procarbazine is administered orally and is well absorbed from the gut. It is rapidly metabolized in the liver, the active metabolites crossing the blood–brain barrier. It is

excreted in the form of metabolites almost entirely by the kidneys.

Dosage varies according to the drug combination used, being 2–4 mg/kg daily (to the nearest 50 mg tablet) for the first week, increasing to 4–6 mg/kg daily until a response or until dose-limiting myelosuppression occurs, in which case treatment is stopped until recovery and may then be resumed at a lower dose such as 1–2 mg/kg daily.

### Adverse effects

The side-effects most frequently encountered are anorexia,

nausea, vomiting and myelosuppression. Both leucopenia and thrombocytopenia may occur, so that the blood count must be monitored and the drug temporarily discontinued if the white cell count drops to  $3 \times 10^9/L$  or the platelet count to  $100 \times 10^9/L$ . Neural effects may occur but are uncommon. They include peripheral neuropathy and central effects, such as depression of consciousness and psychotic behaviour. Other side-effects including hepatic impairment, rashes and interstitial pneumonitis have been described [967]. A disulfiram-like reaction may occur with alcohol.

# SMOKING

IAN A. CAMPBELL

Half of all regular cigarette smokers will eventually be killed by their habit [1]. In 1995 in developed countries some 2 million deaths could be attributed to tobacco, in developing countries 1 million. Within 30 years these figures are likely to increase to 3 and 7 million respectively [2]. Smoking increases the absolute number of deaths from lung cancer, cancer of other respiratory sites, chronic bronchitis/emphysema and cor pulmonale. Deaths from ischaemic heart disease and cerebrovascular disease are advanced by smoking without an increase in the absolute number [3]. Stopping smoking, even in middle age, reduces the risk of dying from smoking-related disease [1] and reduces disability [4]. Since the initial reports by Doll and Hill [5–7] and Wynder and Graham [8] the Royal College of Physicians and the US Surgeon General, among others, have reported further on the harm caused by smoking and on the benefits of giving up the habit [4,9–14]. Yet in the UK 29% of adult males and 28% of females still smoke regularly and there is some evidence that smoking among children is increasing [15,16].

Smoking usually begins for psychosocial reasons, such as parental smoking, curiosity, peer pressure, rebelliousness and assertion of independence [17]. Once it becomes regular the pharmacological properties of nicotine are a major influence on the persistence of the habit [18], which appears to become advantageous to mood and/or life response [19]. Russell [20] described cigarette smoking as 'probably the most addictive and dependence-producing form of object-specific self-gratification known to man'. London drug users rated tobacco as their most needed drug, more than heroin, methadone, amphetamine, cannabis, LSD or alcohol [21]. Yet the manufacture and sale of cigarettes remain universally legal and advertising is permitted in all but a handful of countries.

## Harm to smokers

### Respiratory system

#### Lung cancer

Lung cancer is the most notorious of the diseases caused by smoking. Compared with non-smokers, death from lung cancer is 8–25 times more common among cigarette smokers [1], with a clear dose–response relationship [1,22]. As smoking has increased among women so have their death rates from lung cancer [23–25], leading to a situation in some areas where lung cancer has overtaken breast cancer as a cause of death [26]. In the USA between the 1960s and the 1980s, lung cancer death rates per 100 000 increased among current cigarette smokers from 26 to 155 in women and from 187 to 341 in men, the markedly steep increase of rates in women reflecting the change in smoking habits in women after the Second World War. Rates among non-smokers were stable [14]. Smoking and asbestos exposure are synergistic in producing bronchial carcinoma in humans. A smoker exposed heavily to asbestos runs nine times the risk of developing lung cancer compared with a smoker who is not exposed to asbestos and 92 times the risk of a non-exposed non-smoker [27,28].

Pipe and cigar smokers have an increased risk of lung cancer compared with non-smokers but are at less risk than cigarette smokers [29,30]. Carcinoma of the upper respiratory tract is increased up to 50-fold among cigarette smokers [1], particularly laryngeal carcinoma. In former cigarette smokers mortality declines with time [4]. Those who change from cigarette smoking to pipe or cigar smoking can lower risk but not by as much as does stopping smoking altogether [31]. Changing to lower-nicotine cigarettes is unlikely to reduce risk much because smokers continue to inhale or even inhale more to compensate [32–36]. Such compensation to maintain nicotine intake means that tar intake can only be substantially reduced by using a cigarette with a very low

tar/nicotine ratio/or, better still, by not smoking at all [37].

### **Chronic bronchitis and emphysema**

Mortality from chronic bronchitis and emphysema shows a relation to cigarette smoking almost as strong as that for lung cancer. Among those smoking 25 or more cigarettes daily mortality is over 20 times higher than in non-smokers [1]. Chronic bronchitis is related much more strongly to smoking than to atmospheric pollution [38]. Fletcher and Peto [39] showed that smoking was associated with irreversible obstructive changes in the airways in some subjects but not in others. Once smoking stopped, the rate of fall of forced expiratory volume in 1 s (FEV<sub>1</sub>) with age reverted to the normal rate. Cough, phlegm and wheeze are directly related to the number of cigarettes smoked daily and improve after cessation of smoking [40,41]. Giving up smoking reduces mortality from chronic bronchitis and emphysema [1]. Tar yield is related to sputum volume [42], whilst reduction in exercise tolerance is aggravated by the high levels of carboxyhaemoglobin [43]. Physical fitness and lung function in healthy middle-aged men were substantially lower in Norwegian smokers compared with non-smokers. Fitness and FEV<sub>1</sub> declined by twice as much in smokers compared with non-smokers in the 7 years of the study. Stopping smoking during the period halved the rates of decline, whilst starting smoking increased them [44]. These findings for lung function were confirmed in a study of Japanese-American men in Honolulu [45]. In the Lung Health Study in the USA, cessation of smoking has again been shown to reduce the age-related decline in FEV<sub>1</sub> in middle-aged smokers with mild airways obstruction, whilst regular use of an inhaled anticholinergic bronchodilator did not influence the long-term decline of FEV<sub>1</sub> [46].

### **Cardiovascular system**

It would be parochial not to describe the importance of smoking as a cause of morbidity and mortality in ischaemic heart disease, cerebrovascular disease and peripheral vascular disease. A cigarette smoker has two to three times the risk of heart attack compared with a non-smoker and a 30–60% greater chance of death from heart attack, whilst heavy smokers aged 45 years or younger have 10–15 times the risk of fatal heart attack [29,47–50]. Three-quarters of smokers who have heart attacks under the age of 50 would not have done so had they not smoked [51]. Patients with angiographically proven coronary artery disease who continue to smoke have a 50% greater risk of dying within 5 years than those who stop [52]. Pipe and cigar smokers are also at risk compared with non-smokers [53].

In men and women the risk of stroke and subarachnoid haemorrhage is increased two- or three-fold by smoking; the heavier the smoking, the greater the risk [1,24,54–57]. In New Zealand it was estimated that just over one-third of strokes could be attributed to smoking, much the same as were attributed to hypertension. The presence of both risk factors increased the risk of stroke by almost 20 times over that of a non-smoker [58]. Over 90% of patients with peripheral vascular disease are smokers, these individuals finding themselves unable to give up smoking even after multiple amputations [59].

Stopping smoking after a heart attack is by far the most important factor in preventing further morbidity and mortality, improving prognosis more than do  $\beta$ -blockers [60–62]. The risk declines over 15 years to that of a non-smoker [63]. Continuing to smoke reduces the beneficial effects of anti-anginal therapy [64]. Men who give up smoking before a heart attack occurs reduce their risk of a first myocardial infarction over the next 5 years to that of a non-smoker, although for heavy smokers ( $\geq 20$  cigarettes daily) the risk takes 15–20 years to decline [65,66]. In women the risk declines quicker than in men, approaching that of a non-smoker 3 years after quitting [67]. Changing to cigarettes with lower tar yields is not an effective means of reducing the risk of myocardial infarction [68].

Stopping smoking reduces the risk of stroke in middle-aged men by a factor of four, benefit occurring rapidly within the first 5 years overall but never being complete in former heavy smokers ( $\geq 20$  cigarettes daily). Benefit was most marked in those who also had hypertension. Switching to pipe or cigar smoking reduced the risk very little [69]. Much the same has been found in women in relation to cerebral thrombosis/haemorrhage, although cessation reduces the risk of subarachnoid haemorrhage in women even more than it does in men [70]. In peripheral vascular disease outcome is influenced less by vasodilator drugs than by smoking cessation [71].

### **Gastrointestinal system**

Oesophageal carcinoma is highly related to smoking, death from this condition being eight times as common in smokers as in non-smokers, with a clear dose-response relationship [1]. The association with pancreatic cancer, although significant, is not as strong and the same applies to stomach cancer [1]. Smoking increases susceptibility to peptic ulcer, impairs healing, and increases the risk and rapidity of recurrence and of perforation [72]; the effect of treatment with histamine H<sub>2</sub> antagonists is reduced if a patient continues to smoke [73,74]. Patients with Crohn's disease are more likely to be smokers, whilst in ulcerative colitis there appears to be an association with non-smoking [75,76].

### Genitourinary system

Men who smoke run two to three times the chance of developing bladder cancer; in women the association is positive but not as strong [77]. Smoking also increases the risk of renal cancer [78].

Carcinoma of cervix is up to four times more common in smokers than non-smokers [79], and although some of this apparent risk is likely to be due to confounding factors, there is a direct relationship [78,80]. Fertility in women is decreased by smoking [81], whilst the menopause occurs 2–3 years earlier in smokers [82].

Men who smoke have increased morphological abnormalities of their sperm [83] and fertilizing potential is reduced [84].

### Miscellaneous systems

Smoking is thought to contribute to cataract, possibly as a result of deposition in the lens of the cadmium from tobacco [85].

Bone density is reduced sufficiently by smoking to increase the risk of postmenopausal fracture [86,87].

Premature facial wrinkling is increased by smoking [88], as is palmoplantar pustulosis [89].

### Mechanisms of harm

Cigarette smoke contains many toxic compounds, including polycyclic aromatic hydrocarbons, tobacco-specific nitrosamines and radioactive polonium as well as radon, all of which are potent carcinogens and mutagens in animals. Presumably the increased incidence of lung and other cancers in humans are related to one or more of these substances [90]. Cigarette smoke causes release of elastolytic enzymes from lung neutrophils and macrophages, nitrogen oxides contained in the smoke cause emphysema in animals, and oxidants in smoke reduce the levels of  $\alpha_1$ -antitrypsin in human and animal lungs [91]. Hopkin and Steel [92] found consistent and significant variation in the response of lymphocytes from different individuals to the cytotoxic effect of cigarette smoke condensate *in vitro*. Polymorphs from patients with emphysema were more sensitive to the cytotoxic effects of cigarette smoke condensate than those from age- and smoking-matched control subjects [93]. The implications for emphysema and carcinoma are clear. Endogenous nitric oxide is important in defending the respiratory tract against infection and in counteracting bronchoconstriction and vasoconstriction. Cigarette smoking reduces exhaled nitric oxide concentration, a reduction likely to contribute to the increased risk of chronic respiratory disease in smokers [94].

Pulmonary epithelial permeability is greater in symptomless cigarette smokers compared with non-smokers and this permeability is correlated with carboxyhaemo-

globin concentration [95] but not plasma nicotine concentration [96]. Besides the implications for bronchitis and emphysema, the increase in epithelial permeability is likely to contribute to the genesis of lung cancer by permitting easier ingress of the chemical and physical carcinogens in tobacco smoke.

Increase in permeability of systemic blood vessel walls to lipids has been suggested as contributing to the cardiovascular risks of smoking [90]. Smoking increases atherosclerosis and a tendency to thrombosis [97]. However, smoking seems related to myocardial infarction independently of its effect on atherosclerosis; in 4000 patients with ischaemic heart disease, myocardial infarction was more common in smokers than in non-smokers with a comparable degree of occlusive disease on the coronary angiogram [98]. This may be related to the loss of oxygen-carrying capacity of the blood due to raised carboxyhaemoglobin levels and to the effect of nicotine in causing increased catecholamines, platelet stickiness and platelet aggregation [90].

### Harm to non-smokers

Passive (or forced) smoking can have deleterious effects on health. In many situations the passive smoker has no choice in the matter, an infringement of rights that in most other instances would be illegal.

Maternal smoking increases the combined mortality in fetal and neonatal life by 28%, and reduces birthweight by 170 g to 320 g [99,100]. It is thought that there is hypoxic damage to the fetus as a result of placental insufficiency caused by nicotine-induced vasoconstriction and by high carboxyhaemoglobin concentrations in fetal and maternal blood [101]. Interestingly, reduced birthweight is also correlated with paternal smoking even after controlling for the mother's habits [102]. Smoking by parents is the most important risk factor for inducing sudden infant death syndrome (cot death). Maternal smoking is more important than paternal, with a fivefold risk if both smoke [103–105]. In the first year of life, children of smoking parents have twice the risk of pneumonia and bronchitis and twice the risk of admission to hospital because of respiratory illness [106–108].

Lung function in children is impaired by maternal smoking, the damage possibly occurring *in utero* as well as in infancy/childhood [109,110]. There is a link between smoking in the home and coughs and snoring in young children [111,112], as well as with acute attacks of asthma and the prevalence of asthma [113–115]. Allowing for associated social and biological factors, smoking in pregnancy leads to retarded reading, mathematical and general ability [116], as well as an increased risk of cancer in childhood [117]. Exposure to environmental tobacco smoke during childhood and adolescence leads to increased risk of lung cancer in adulthood [118].

Exposure to tobacco smoke can cause cough and breathlessness in non-smoking patients with chronic bronchitis and emphysema and can induce attacks of asthma [4]. In 1980, White and Froeb [119] found evidence of small airways disease in non-smokers who were chronically exposed to tobacco smoke. Non-smokers exposed to tobacco smoke in their workplaces had more cough, phlegm, shortness of breath, eye irritation, 'chest colds' and lost days from work due to 'chest colds' [120], with significant effects on lung function [121]. Passive smoking at home and at work is associated with breathlessness, cough, sputum, asthma and allergic rhinitis [122]. Patients with asthma experienced symptoms, had increased airway irritability and showed a fall in FEV<sub>1</sub> when exposed to environmental tobacco smoke for 1 h [123].

In 1981, in both Greece and Japan, passive smoking by wives was reported to increase their risk of lung cancer [124,125]. Since then the weight of evidence has been such that five independent expert groups have concluded that passive smoking causes lung cancer in non-smokers, increasing the risk by 10–30%. In the UK, at least 300 deaths every year from lung cancer in non-smokers can be attributed to the effects of passive smoking [126].

Passive inhalation of cigarette smoke can worsen angina [127]. Death from ischaemic heart disease is significantly higher for non-smoking spouses who live with smokers compared with those not exposed to passive smoking in the home [128,129]. Wells [130] reviewed the evidence linking passive smoking to ischaemic heart disease and concluded that passive smoking increased the coronary death rate among people who never smoked by 20–27%, a finding supported by a later meta-analysis [131].

## Stopping smoking

Much has been achieved in the last 25 years, but the aim must be a further reduction and eventual complete eradication of the smoking habit. Education of health professionals, the general population, civil servants, politicians and governments is a key step. In itself education should reduce smoking but it is also important as a prerequisite to more effective restrictive and legislative steps. An educated population will understand and respect restrictions [132]. Politicians must be persuaded not only that smoking is harmful to both active and passive smokers but also that, given enough educational preparation, smokers will recognize that cigarette tax is not reason enough to change their vote. After a period of education the Norwegian Tobacco Act of 1975 banned all advertising of tobacco products, required all packets to be labelled with a symbol and text pointing out their health dangers, prohibited sales to those under 16 years old and allowed the Ministry of Health and Social Affairs to issue regulations concerning content, weight, filters, etc. of tobacco

products. Further legislation has been accepted in Norway, i.e. only non-smokers are offered new jobs in the asbestos industry and smoking is not allowed in such work premises. Between 1975 and 1980 smoking fell markedly in men and among young people of both sexes, whilst the increase among Norwegian women was halted. In 1980 the Government increased the price of cigarettes by 30%, with accompanying publicity about the underlying medical reasons for this move; simultaneously the Norwegian Council on Smoking and Health ran an advertising campaign emphasizing the financial savings if a person stopped smoking.

Smoking in children is related to whether their parents smoke and, to a lesser extent, peer pressure, which itself is dependent on parental habits. Thus moves to reduce smoking in adults will reduce smoking in children. Increasing the real price of cigarettes by relentless tax rises is a most effective means of reducing smoking in adults [133]. Atkinson and Townsend [134] proposed a policy for the UK which they calculated would reduce smoking by 40%, reduce morbidity, increase longevity but would not increase net cost to the exchequer.

The importance of banning advertising of cigarettes and other tobacco products has been demonstrated not only in Norway but also in New Zealand, Finland and Canada; consumption falls among children and adults but advertising and publishing industries are not disadvantaged. The ethics of advertising a product that is so dangerous to health should continually be questioned in public. Over 70% of the UK population are now non-smokers and they should press for their right to breathe clean air. Evidence of damage from passive smoking was sufficient to persuade Australian and Swedish courts to award compensation to harmed passive smokers and to relatives of deceased passive smokers. Courts in the UK and the USA are likely to respond similarly. Employers and organizations fear this consequence, a fear that should be exploited when they resist health and nuisance arguments for smoke-free environments. Smoking should not be permitted on healthcare premises except in very special circumstances and then only in private. In the current purchaser-provider situation in the UK National Health Service, purchasers (health authorities and GPs) should require smoking to be banned from all but specially designated areas in healthcare premises and should include such a policy and measures to monitor its effectiveness in contracts with providers, e.g. hospitals. Ultimately, staff and visitors should not be allowed to smoke in healthcare premises, and patients only in very exceptional circumstances.

## Smoking cessation in general practice

With simple advice to stop smoking and with a warning of possible later follow-up, GPs can motivate more of their

patients to stop smoking and some 5% will still be abstinent 1 year later [135]. On average any GP could thereby achieve 25 long-term successes each year. If every GP in the UK were to do this, then initially more than half a million people would stop smoking. Health risks are the most frequent reason for quitting; of successful ex-smokers who gave illness as a reason for stopping, 54% said that they had done so on a doctor's advice. In 1967, only 20% of smokers reported that their doctor had advised them to stop or cut down [21]. Disappointingly, in a survey in 1982 Inman [136] found that only 15% of GPs encouraged the smokers among their patients to stop. It will be interesting to see whether these figures have changed during the 1990s, with the introduction of government incentives to GPs to encourage their patients to stop smoking. A GP's advice increases the proportion intending to stop and the proportion who try to stop, rather than increasing actual success rates among those intending or trying to stop [135].

In Oxford, a further study showed an 11% quit rate at 1 year in a control group, 15% in a group given advice plus a booklet, 17% in a group where the patient's expired carbon monoxide level was measured at the time of giving advice plus booklet, and 13% in a group where an offer of a visit from a health visitor replaced the carbon monoxide measurement as part of the strategy. Claims of abstinence were verified by urinary cotinine measurements. The combined result of the active groups was significantly better than the control group, but there was no difference between the active treatments nor between any one treatment and control [137].

In Sydney, Richmond *et al.* [138] gave intensive advice to patients who agreed to join a smoking cessation programme and compared this with a control group where the patient was asked to participate in a study of 'smoking and health'. At the initial encounter the control subjects completed a questionnaire, had blood taken for carboxyhaemoglobin estimation and had their FEV<sub>1</sub> measured. A follow-up appointment in 6 months was arranged. The active group received advice and a booklet in addition to the questionnaire and carboxyhaemoglobin and FEV<sub>1</sub> measurements, and were given five follow-up appointments over the next 6 months. Advice was repeated at each follow-up visit. At 3 years, 2% in the control group were abstinent compared with 23% in the active group ( $P < 0.01$ ), using salivary cotinine to validate claims of cessation. However, in another study in New South Wales neither simple advice nor a structured behavioural change programme resulted in a statistically significant increase in the number of patients stopping smoking, 5% in the structured group remaining abstinent for 12 months compared with 1% in the simple advice group or control group [139].

In the USA, physicians advised 2707 patients to stop smoking and then referred them for further help from a

nurse. The nurses either provided a two-page pamphlet or one of three nurse-assisted interventions: (i) giving advice on how to stop; (ii) group cessation; or (iii) combination of (i) and (ii). At 12 months the group given nurse-assisted interventions did better than the group given a pamphlet only (7% vs. 3.9% validated cessation) [140].

Following the promising results of nicotine chewing gum in the setting of smoking withdrawal clinics, Russell *et al.* [141] tried it in general practice. At 1 year they obtained a validated success rate of 8% in a group receiving nicotine gum plus advice, compared with 4% in a group receiving advice plus a leaflet and warning of follow-up and 4% in a group that just completed a questionnaire. The design of the study did not include a group receiving placebo chewing gum. Jamrozik *et al.* [142] did compare nicotine gum with placebo in 199 of the 429 patients who had failed to give up smoking in their earlier study and who then agreed 'to try an anti-smoking chewing gum' as an aid to stop smoking. Validated success rates at 6 months were 10% vs. 8% in this motivated but nevertheless 'hard case' population. Nicotine gum has been compared with placebo (confectionery gum) in South Wales in smokers routinely consulting their GP. The GP's usual advice to stop smoking was given to both groups and to an advice only group. At postal follow-up at 1 year, claims of sustained abstinence for at least the last 6 months were then verified by measurement of expired air carbon monoxide levels. The nicotine gum resulted in 3.1% success, placebo gum 2.2% and doctor's advice only 1.3%, differences that were not statistically significant [143]. In a further British study Marshall and Raw [144] compared intensive follow-up in 200 patients who wished to stop smoking and who agreed to try nicotine gum as an adjunct. At 1 year they recorded 15% and 14% success rates.

In Sydney 450 smoking patients were allocated to structural behavioural change plus nicotine gum or structural behavioural change without nicotine gum or GP advice with nicotine gum. Continuous abstinence from the end of 1 week to 1 year (validated) was 9% for the groups undergoing structural behavioural change and 6% for the other group [145]. The clear and significant benefit from nicotine gum when used in specialized smoking cessation clinics is not evident when it is used in general practice [146].

Transdermal nicotine was used in general practice in Switzerland and, in middle-aged, dependent smokers seen monthly for 3 months, was shown to produce better results than placebo patches. Further studies led to the conclusion that transdermal nicotine would work in motivated smokers (20 or more cigarettes daily) when used in specialized smoking cessation settings, but emphasized the need to provide adequate support and counselling if success rates as good or better than the 26% reported by the Transdermal Nicotine Study Group were to be achieved [147]. In a general practice study in Oxfordshire,

treatment with transdermal nicotine in addition to advice and support from practice nurses resulted in 10% continuous abstinence at 1 year in the active group compared with 7% in the placebo group ( $P < 0.05$ ) [148]. Early abstinence from smoking was the strongest predictor of sustained cessation [149]. In another study, extending over 30 general practices in 15 English counties, Stapleton *et al.* [150] compared nicotine and placebo patches in patients who all received brief advice from the GP plus a booklet, both groups receiving brief support and follow-up at regular intervals throughout the year. Validated continuous abstinence rates at 1 year were 9.6% for the nicotine group and 4.8% for the placebo ( $P < 0.01$ ). The patch enhanced cessation during the first week and reduced relapse during the second week. The majority of eventual successes had stopped smoking during the first week. Adverse effects were limited to moderate to severe local irritation or itching of the patch site in about 15% of the patients.

### Smoking cessation in hospital patients

Patients attending hospital with smoking-related diseases who nevertheless continue to smoke up to the time of their attendance must, by definition, be a 'hard-core' population. They are suffering from symptoms and conditions which, in all probability nowadays, they know are related to cigarette smoking and yet they have not stopped before coming to the hospital. They must be a different group from patients encountered in general practice and from smokers in the general population who are recruited or seek help from smoking cessation schemes.

At a London chest clinic, simple advice by the physician, resulted in an abstinence rate over 6 months of 18–23%, although these claims were not validated objectively [151]. In another study, patients with airways obstruction who were advised by a chest physician to reduce or stop smoking were more likely to do so than those not so advised. In the same study, it was shown that the wearing of a white coat by a clinical psychologist who interviewed the patients after they had seen the chest physician increased the numbers claiming to have stopped or reduced their smoking [152]. For patients recovering from myocardial infarction, firm advice from a physician, repeated by junior staff and nurses and reinforced by written advice, special follow-up clinics and home follow-up by community nurses, resulted in 63% claiming abstinence at 1 year. Over 85% of these patients stopped while in hospital, the remainder during follow-up. Abstinence was not verified but even allowing for a 30% rate of false claims the calculated success rate of 40–45% is good. In the control group who received conventional advice without follow-up only 27.5% claimed abstinence [153]. Strong, uncompromising advice to patients attending a post-myocardial infarction clinic resulted in 42% verified abstinence rates, although

in this study the period of abstinence was not stated [154].

In the large multicentre trial run by the British Thoracic Society, nicotine chewing gum was used as an adjunct to physician's advice but it proved no more effective than placebo gum or an advisory booklet or the advice alone; at the end of 1 year 10% of these patients with smoking-related diseases had successfully stopped smoking for at least the previous 6 months. Chewing gum clearly aided abstinence for 1 and 3 months but there was no difference between active and placebo gums [155]. Men did better than women (12.5% vs. 5.3% success), success rate increased with age in both sexes and people with heart disease did better than those with any other diagnosis. If the most important other person to the patient was a non-smoker then success was more likely, whilst single or married men did better than separated or divorced men. Confidence in ability to stop was a predictor of success in men but not women. Cigarette consumption, social class, concern about weight gain and perceived benefit of stopping smoking did not relate to success. Patients cited worry or anxiety as things that made them want to smoke after they had stopped and those who stated that they still craved or found it difficult to do without cigarettes were more likely to relapse [156].

This trial was criticized for lack of early support after the initial advice from the physician. That such support might increase success rates in patients was suggested by the study from Sweden in which nicotine gum plus group therapy gave a validated success rate of 29% at 1 year compared with 16% for placebo gum plus group therapy. One-third of the subjects were self-referrals to the clinic or hospital, whilst two-thirds were referred by physicians [157]. In two further multicentre trials in the UK in outpatients with smoking-related diseases, the British Thoracic Society compared physician's advice alone with advice backed up by a signed agreement to try to stop smoking by a target date, two visits from a health visitor in the first 6 weeks and encouraging follow-up letters from the physician (five in the first 6 months). The design of the trials allowed assessment of the follow-up letters, the health visitor and the signed agreement as separate parts of the package. It was hoped that out of the trials would emerge an effective, simple strategy that would prove superior to a doctor's advice alone and would also be within the human and financial resources of hospitals and chest clinics. The results indicated that physician advice alone would persuade 5% of outpatients with a smoking-related disease to stop smoking and that subsequent postal encouragement would increase the cessation rate by more than half as much again. The signed agreement and visits by health visitors did not affect outcome. Thus a simple method based on advice followed by postal encouragement to stop smoking has been shown to be more effective in hospital outpatients than advice alone. Even these

modest increases in cessation rates are worthwhile if they have the potential to be applied on a large scale [158].

In a chest clinic in South Wales, cigarette-smoking patients referred just for chest radiography were allocated at random to a control group (radiography only) or to an active group who had radiography and were given a pocket-sized, 13-page advisory booklet on smoking. At 1 year, claims of abstinence were verified with measurements of expired air carbon monoxide levels and demonstrated 6.5% success with the booklet compared with 2.7% in the controls ( $P=0.09$ ). If this effect could be shown to be real rather than due to chance, then the application of such a strategy on a wide scale would result in significant numbers giving up smoking at very little cost, perhaps as little as £10 per successful ex-smoker [159].

A study at two clinics in Ann Arbor Veterans Administration Medical Center (Michigan, USA) compared a leaflet on smoking with a self-help booklet plus a 20–30 min session from a trained counsellor and with the latter strategy plus individually tailored follow-up treatments by telephone and post. At 6 months, success, as determined by those who claimed not to have smoked for at least 1 month prior to answering and with measurement of urinary cotinine to verify their claims, was 6% in the active treatment groups compared with 1% in the control group [160].

The work by Hjalmarson [157] has been taken further in a hospital in South Wales, where a medical secretary with good interpersonal skills has been used as a smoking cessation counsellor to reinforce the physician's advice to stop smoking. In addition to intensive early support from the counsellor (three sessions in the first month and further sessions at 2 months and 3 months), patients were randomized to nicotine or placebo chewing gum. At 1 year, the validated sustained abstinence rate was 20%, with no difference between nicotine and placebo [161]. The same design was used in a further study of patients attending hospital (inpatients and outpatients) with smoking-related diseases, but instead of gum transdermal nicotine was compared with placebo patches; at the end of the year 21% in the active group and 14% in the placebo group said that they had not smoked throughout the period from week 12 to week 52 and measurements of expired air carbon monoxide levels at 12, 26 and 52 weeks confirmed these claims [162]. Although this difference was not significant at the 5% level, it does indicate that a further study large enough to answer this question should be conducted, such a study ideally including a third group receiving just support and advice. These two studies showed that success rates two to four times greater than those obtained in the studies by the British Thoracic Society [155,158] and comparable to the results achieved in Sweden [157] could be obtained using relatively unsophisticated staff under routine health service conditions. The counsellor continues to achieve 20% sustained suc-

cess at 1 year, a service which, in terms of cost per life-year saved, is more cost-effective than  $\beta$ -blockade for mild to moderate hypertension [163].

### Smoking cessation in other clinical settings

Family planning clinics and antenatal clinics provide good opportunities for influencing the smoking habits of women. In San Francisco, Coates *et al.* [164] showed that 3–5 min of advice from the doctor or midwife did better than just posters plus a video shown in the waiting room, cotinine-verified success rates at 1 year being 0.1% for the control group, 2.4% for posters plus video, and 3.7% for the doctor's or midwife's advice.

At an antenatal clinic staffed by family practitioners in Toledo City, pregnant women were just advised by the physician in the usual way to stop smoking or were provided with the American Lung Association's *Freedom from Smoking for You and Your Baby* booklet or were shown an educational videotape about smoking in pregnancy. Smoking status was assessed objectively 2–3 weeks prior to delivery when abstinence rates ranged from 4 to 9% with no significant difference between the three interventions [165]. A similar study by Messimer *et al.* [166] had shown 5–15% cessation rates, the differences between these two studies appearing to be due to the fact that the populations were markedly different, with more people in the study by Messimer *et al.* being married, more in employment and fewer from ethnic minorities.

### Smoking cessation clinics

Traditionally, smoking cessation clinics have offered treatment to self-selected clients and emphasized group therapy and educational approaches. In a review of the results of several studies in such clinics, Raw [167] found similar long-term success rates of between 15 and 20%. Success rates of up to 80% could be achieved in the first month but most clients relapsed in the next 3–4 months. He found no evidence that tranquillizers helped people to stop smoking; results of hypnosis were mostly anecdotal, with controlled investigations and biochemical verification of abstinence sadly lacking. No specific effect could be demonstrated for electrical aversion therapy, whilst other aversion therapies in the form of rapid smoking or blowing warm, smoky air into the faces of smokers gave success rates of around 60% at 6 months but, as Raw concluded, 'it is difficult to be sure whether the aversive components or the inevitable, non-specific, therapeutic variables in these experimental situations are more important'. More recently, the antidepressant amfebutamone (bupropion) has been shown to increase the point-prevalence cessation rate at 1 year in smokers without current depression [168]. Nicotine chewing gum was first shown to be effective in studies conducted in smoking

cessation clinics. In London, at the Maudsley Hospital's smokers' clinic, 31% of patients treated with nicotine chewing gum and usual supportive treatment abstained from smoking for 1 year compared with 14% in the placebo gum group ( $P < 0.05$ ) [169]. When transdermal nicotine is used within the setting of a smoking cessation clinic and in populations of healthy smokers who volunteer to attend, it too produces an improvement over placebo patches [170–172]. Nicotine by inhaler or nasal spray has been studied in smokers' clinics based in hospitals. At the Maudsley Hospital, validated continuous abstinence rates throughout a year were achieved by 26% of the patients assigned to nicotine nasal spray plus usual supportive group treatment, whilst with placebo the abstinence rate was 10% ( $P < 0.01$ ) [173]. In Reykjavik, the use of nicotine nasal spray increased abstinence rates up to 6 months but not to 1 year [174]. In these studies the majority of the patients experienced local irritant effects but only a small minority ( $< 1\%$ ) discontinued the spray because of adverse effects.

In Copenhagen, volunteers recruited by newspaper advertisements received either 3 months of nicotine inhaler or placebo inhaler in the context of minimal levels of advice and support. Continuous abstinence rates (verified) after 1 year were 15% for the active inhaler and 5% for the placebo ( $P < 0.02$ ) [175]. In Sweden, Hjalmarson *et al.* [176] obtained 27% continuous abstinence with nicotine inhaler and 15% with placebo in a mixed population of patients (one-third) and newspaper-recruited volunteers (two-thirds).

The best smoking cessation clinics are labour intensive and produce good results, but the majority are labour intensive and produce mediocre or poor results [177]. Chapman [178] has cogently argued the case for their abandonment, pointing out that they reached 0.5% or less of the smokers in the UK who wanted to stop and were not cost-effective. To be effective on a population basis and to be cost-effective, smoking cessation programmes and techniques must be capable of being inexpensively incorporated into a delivery system that involves significant numbers of smokers, including patients who smoke. Humerfelt *et al.* [179] have recently shown how this can be done with postal methods applied to young Norwegian men at increased risk for smoking-related lung disease.

### Mass media methods

In 1975, two UK television programmes on smoking increased the numbers of smokers trying to give up by 27%. By virtue of this extra motivation the programmes produced a useful effect on long-term abstinence [180]. After a television programme on the health hazards of smoking, two-thirds of those requesting a postal smoking cessation kit were sent the kit, whilst one-third were

chosen at random as controls and did not receive the kit. Validated cessation at 1 year was 9% in recipients of the kit compared with 7% in the control group ( $P < 0.05$ ) [181]. Leaflets on the reasons for stopping smoking increased abstinence rates at 1 year by 30% among responders to a newspaper advertisement (F. Ledwith, personal communication, 1982). Radio and newspapers were used to advertise the 'Quit and Win' contest in Wales in 1990 in which the reported sustained quit rate at 1 year was 30% (unvalidated). The estimated cost for each year of life saved by the contest was £42 [182]. Reid [183] calculates that mass campaigns involving television are probably cost-effective; the cost per year of life saved would be in the region of £6–12, about the same as brief advice from a GP. He argues that media publicity not only reduces smoking but also creates a climate of opinion in favour of effective measures such as fiscal policy.

Continued efforts on all the aspects covered in the preceding sections will be necessary to renew the downward trend shown in Fig. 10.1, a trend which should give some satisfaction not only to those who have obtained and published the evidence for the dangers of smoking and the benefits of stopping but also to those who have campaigned for society and government to reduce smoking.

### Safer cigarettes

No cigarette is safe. Progressive reduction of tar yields over the last 20 years has contributed to the reduction of deaths from lung cancer at all ages among men and to

Fig. 10.1 Smoking prevalence in the UK, 1972–96 (16 years-old and over), (General Household Surveys 1972, 1984, 1994, and 1996.)

deaths under 65 years among women. If nicotine is reduced to an unduly low level, compensatory smoking occurs, with increase in hazard from the increased smoke, tar and carbon monoxide inhaled. The introduction of synthetic tobacco substitutes in cigarettes to replace some of the natural tobacco was not successful in 1977 when the substitutes were based on modified cellulose [184]. Experience with glycerol particle cigarettes does not suggest that they are likely to be any more successful as substitutes [185].

### **Smoking and weight**

The evidence for an inverse relation between cigarette smoking and body weight is convincing. Smokers tend to weigh 2–5 kg less than non-smokers of comparable age and height and many studies have shown that smokers who quit gain a similar amount [156,186]. Animal studies suggest that nicotine is responsible for the effects of smoking on weight; in humans it has been established that cigarette smoking increases 24-h energy expenditure by approximately 10% and that this effect is mediated by nicotine [187]. In modern society smoking is widely perceived as an effective strategy of weight control, especially by women. It should be made clear, especially to adolescents and adults, that smoking is an unhealthy way to control weight. In the meantime further studies should seek a more precise understanding of the mechanisms of smoking-related weight loss, and strategies of weight control for smokers who try to give up should be developed.

### **Smoking in the workplace**

Many employers have recognized the importance of controlling smoking in the workplace, not only because this practice reduces disease and days off sick among their workforce but also because it reduces the likelihood that non-smokers in their workforce might acquire a condition induced by passive smoking and seek compensation. Being unable to smoke at work contributes to a reduction in smoking prevalence in workforces, with prevalence declining at about twice the rate found in the general community [188]. Minimal smoking intervention programmes based on the use of videotapes produced long-term abstinence rates of under 10% in four companies in the UK. The addition of four, short consultations with the occupational health nurse, coupled with the use of nicotine chewing gum, resulted in 16% sustained cessation at 1 year in the intervention group compared with only 2% in the control group [189]. The organizations ASH and QUIT now offer advice and help to employers who wish to reduce smoking in the workplace.

### **Children and smoking**

Children are more likely to become smokers if their parents smoke [190]; pressure from peers is also important. At age 15, 26% of boys and 30% of girls in the UK are regular smokers. The number of children aged between 11 and 15 who reported smoking at least one cigarette per week rose from 10% in 1993 to 12% in 1994. In this age range, 70% of those who were regular smokers smoked more than 20 cigarettes a week and 25% smoked at least 10 cigarettes daily [16]. In the UK very few people take up smoking after the age of 18 years. Besides the influence of parents and peers, children are influenced towards smoking by the availability of cigarettes, advertising and the portrayal of smoking in films, magazines and literature. Cigarette prices also have an effect. Taking up smoking is associated with early onset of cough, production of phlegm and shortness of breath on exertion in children and adolescents. Studies detailing the deleterious effect of smoking in children and adolescents are summarized by Charlton [17], who also underlines the fact that children who smoke become addicted to nicotine quickly and at an early age. Of the methods that she suggests for preventing and reducing smoking in children and adolescents, by far the most important is government action to ban cigarette advertising, increase the price of cigarettes and create a smoke-free norm. The study by Porter [191] has established that measures reducing the exposure of an uncommitted adolescent to peer-group smoking decreases the chances of tobacco dependence in adulthood.

### **Smoking and the developing world**

Worldwide deaths from cigarettes are expected to increase from 3 million currently to about 10 million by the year 2020 [192,193]. Patterns of smoking are different in developing and developed countries: in the developing countries over 50% of men smoke whilst only 10% or less of women smoke, compared with developed countries where 25–30% of both men and women smoke. As in developed countries, smoking starts among young people and for much the same reasons. Consumption of tobacco is increasing in eastern Europe and Asia, the latter continent accounting for about half the world's cigarette consumption. As the market for tobacco shrinks in the developed nations, the multinational tobacco companies are targeting the developing countries. The human and economic burden of medical and health costs, coupled with lost productivity, loss of the use of land that could be used to grow food and loss of the foreign exchange paid in importing cigarettes will all impose severe penalties on the developing nations.

Medical and paramedical professionals from the developed world have a responsibility to influence medical

opinion in developing countries and via this means alert governments to the problems that increased smoking will cause. The World Health Organization and international non-governmental agencies should have a programme on influencing smoking in developing countries. Governments should be encouraged to develop national tobacco control policies, which would include bans on tobacco promotion, discouraging smoking in children and adolescents and the creation of national non-smoking norms.

Taxing tobacco in developing countries will have as strong an impact as it has done (and can continue to do) in developed countries.

# AIR POLLUTION

ANTHONY SEATON

Two great social revolutions have been the main contributors to anthropogenic air pollution. The first of these was the Industrial Revolution, which started in Britain and western Europe in the eighteenth century and resulted in the growth of cities to house the workers in the new factories. The fuel of the Industrial Revolution, in both the factories and the houses, was coal and the buildings of the towns and cities became black with the sooty smoke. Throughout the first half of the nineteenth century the major conurbations of western Europe were noted for their winter-time smoky fogs, or smogs, during which it was commonplace in these cities not to be able to see across the street. It is important to realize that this epoch of rapid industrialization is still continuing in other parts of the world and that uncontrolled burning of coal and other fuels may constitute one of many threats to health in developing countries.

The second important contributor to air pollution has been the revolution in mobility, characterized by increasing ownership of cars and use of motor vehicles for transportation of goods. This rapid change has occurred as a consequence of greater general prosperity and of the ready availability of cheap fuel. Prosperity is relative and even in many poorer countries there has been a massive increase in the use of cars and lorries wherever the economy has improved, to the extent that some of the worst traffic pollution in the world now occurs in cities such as Calcutta and Cairo. This has resulted in a change in the type of pollution in places where coal burning has been reduced and traffic has increased, so that the smoke may contain less black matter and sulphur dioxide but more nitrogen oxides and other chemicals. The increased output of these substances has also led to greater secondary pollution by the photochemical production of ozone.

It has been a characteristic of cities since their populations started to increase in the Industrial Revolution that the poorer people have lived in the more polluted parts, downwind and close to the sources of the smoke. Those who could afford to bought their houses upwind of, and

distant from, such areas. It is perhaps because of this, and because of the other accompanying social disadvantages that led to poorer health among the less well-off, that it took the medical profession so long to recognize the harmful effects of air pollution on health. It was not until the 1950s that a succession of major air pollution episodes, most notably in the Meuse valley in Belgium and in London, were seen to be associated with excess numbers of deaths and hospitalizations from respiratory and cardiac disease. Investigation of the effects of the severe London smog of 1952 showed that during the week of the episode some 4000 excess deaths occurred in the city (Fig. 11.1) and this resulted in the first serious scientific studies of air pollution and its effects on health [1]. The evidence was so compelling that the British Parliament (which of course has its seat in the very place where the smogs were at their worst) enacted legislation, the Clean Air Act 1956, that aimed to control the burning of smoky fuel in towns and cities. The benefits of this legislation rapidly became apparent with the abolition of winter smogs, and it was widely believed that the problem of air pollution had been solved.

Over the past two decades it has slowly become apparent that the problem of air pollution still exists. Ecologists have drawn attention to the effects of exported pollution in the acidification of rivers and lakes in other countries, with damaging consequences on trees and aquatic life. This has occurred as a result of concentrating electricity generation in rural areas, in large coal-burning power stations with tall stacks, an economical and rational means of reducing urban pollution but one with consequences that were unforeseen at the time of their building. Others have drawn attention to the damaging effects of urban pollution on the fabric of buildings and to the economic costs involved. With respect to worldwide effects on health, the increasing combustion of fossil fuels and the consequent increase in carbon dioxide concentration in the air is likely to be a major contributor to global temperature rise, with possible secondary effects on rainfall in arid areas, rise in sea level and the distribution of diseases. Moreover, the

Fig. 11.1 Daily mortality in London in December 1952 compared with the previous year. During the week-long episode 4000 excess deaths occurred.

release of certain chemicals that destroy stratospheric ozone has increased access of ultraviolet rays to ground level and may be contributing to the increase in skin neoplasms among fair-skinned people. This generally increased awareness of the effects of the anthropogenic use of energy on the environment has been accompanied by a resurgent interest in possible more direct effects of the current types and concentrations of air pollution on health, and epidemiological studies have shown that this problem has not gone away. Finally, it has been recognized that the indoor, domestic environment may also contribute to ill-health, particularly by the production of oxides of nitrogen by gas appliances. This chapter considers the main outdoor and indoor pollutants, their sources and their effects on the respiratory system.

## Main pollutants

### Particles

The popular concept of airborne pollution is soot, more of a nuisance than a threat to health. Indeed, the original and still most widely used method of measuring particulate air pollution is drawing the air through a filter paper and measuring the blackness of the stain produced, the black smoke method. However, even in the 1960s, pioneering studies showed that the particles were of an enormous size range and contained vast numbers smaller than  $1\mu\text{m}$  in diameter [2]. It was also shown that the particles were strongly acidic, reaching a pH of as low as 2. The current standard method for characterizing particles uses an instrument with an orifice that selects those below about  $10\mu\text{m}$  in aerodynamic diameter, these being most likely to reach and be deposited in the lung acinus (the so-called  $\text{PM}_{10}$ ). The deposition of such particles is shown in Fig. 11.2; deposition at alveolar level in terms of proportion of

Fig. 11.2 Deposition of particles in the lung in relation to particle size. (From Department of Health Committee on the Medical Effects of Air Pollution [3] with permission.)

particles increases progressively as diameter decreases, reaching a peak at around  $30\text{nm}$ . In terms of numbers of particles, therefore, the greatest deposition is in the range below  $0.5\mu\text{m}$ ; however, since larger particles are heavier, in terms of mass deposition is greatest above this size. This fact is crucial to understanding the toxicity of particles. Both methods of measurement, black smoke and  $\text{PM}_{10}$ , use the same gravimetric units ( $\mu\text{g}/\text{m}^3$ ) but there is no very close relationship between them because of the variable composition of particles, some sources such as diesel exhaust producing less black particles than others such as coal burning. Recent studies have confirmed that urban airborne particulate pollution contains billions of small particles in every cubic meter of air, even when the total mass is only a few micrograms [4] (Fig. 11.3). The finest of these, around  $20\text{--}30\text{nm}$  diameter, are generated by combustion and are short-lived, aggregating into larger particles resembling bunches of grapes and thus maintaining a high surface area, with an average diameter around  $100\text{nm}$ ; these two separate peak concentrations can be seen in Fig. 11.4.

The adoption of  $\text{PM}_{10}$  as a standard measure of urban air pollution has recently been recognized as problematical. The usual measuring instrument is called a tapered element oscillating microbalance (TEOM). This gives a continual read-out and operates at a temperature of  $60^\circ\text{C}$  in order to remove water. This also drives off other volatile components, thus underestimating the weight found by other filter-weighing methods. This may not be significant if the volatiles are non-toxic but at present this (though possible) is not known. More importantly,  $\text{PM}_{10}$  includes a disproportionate contribution from coarser resuspended particles in the  $1\text{--}10\mu\text{m}$  range. These are very unlikely to

**Fig. 11.3** Average daily counts of particles less than 500 nm in diameter in Aberdeen, a relatively unpolluted city, over 3 months. Mean counts range between 3000 and 25 000/mL (i.e. up to 25 billion/m<sup>3</sup>).

**Fig. 11.4** Typical size-number distribution of airborne particles below 500 nm measured in Aberdeen showing peaks at about 30 and 100 nm diameter.

be toxic at the low concentrations found in urban air but may seriously distort measurements made in dry, dusty parts of the world. There is thus a move towards measuring particles less than 2.5  $\mu\text{m}$  ( $\text{PM}_{2.5}$ ) but here the proportionate loss from evaporation in the TEOM is likely to be even greater. At present the best metric for measuring particulate air pollution is not clear, but is likely to depend on a better understanding of the toxicity of the different size fractions within  $\text{PM}_{10}$  (see below).

The chemical composition of airborne particles relates to their size. Larger ones, above about 2.5  $\mu\text{m}$  in aerodynamic diameter, include mineral particles produced by abrasion of rocks and wind dispersion of soil, and salt from sea spray. Carbon particles produced by combustion processes are found in all size ranges; in the smallest sub-micrometre range they may have complex shapes and large surface areas, with the potential to carry adsorbed chemicals deep into the lung (Fig. 11.5). The smallest particles are produced by condensation of gases arising from combustion and comprise predominantly ammonium sulphate and nitrate. The composition of particulate clouds also clearly relates to the source of the pollution, and it is important to remember that  $\text{PM}_{10}$  measured in different places is often very different chemically. However, in cities the main sources are combustion, either in vehicle engines or from oil burning in houses and factories. The petrol engine fitted with a catalytic converter makes a relatively

**Fig. 11.5** Electron micrograph of diesel particles collected on filter. The pores in the filter are approximately  $0.2\mu\text{m}$  in diameter and the particles are primarily aggregates of much smaller ones with high surface area. (Courtesy of Professor Roy Richards.)

small contribution, the main source currently being diesel combustion. In other places, large industrial complexes such as power stations, chemical or steel works may act as important point sources of particulate pollution, while natural sources such as forest fires, volcanoes and dust storms make the major contribution in some parts of the world.

### Sulphur dioxide

Sulphur dioxide is also produced mainly by combustion of fossil fuels, principally coal and oil, and naturally by volcanic activity. It is oxidized at a rate of about 1–10% per hour in the atmosphere to sulphur trioxide, which is then hydrolysed to sulphuric acid. As an urban pollutant it is now only important in places where coal is still widely burned, and concentrations have declined rapidly in most western cities since the 1960s. Concentration of power generation in large rural plants has meant that the main sites of sulphur dioxide pollution are now in the countryside, downwind of the source, when winter temperature inversions bring the plume to ground level. This method of solving urban pollution problems by creating a new problem of long-distance acidification of soil and water has already been mentioned.

### Oxides of nitrogen

While the major worldwide sources of nitrogen dioxide are volcanoes, thunderstorms and bacteria, the most

important sources from the point of view of human health, because of their local concentration, are fuel combustion in vehicles and industrial processes. In this respect, in contrast with particles and sulphur dioxide, gas burning is also important and domestic use of gas for cooking and heating is often the main source of exposure of individuals to nitrogen dioxide. Cigarette smoke is another important source. In most cases the combustion processes produce nitric oxide but this is rapidly oxidized in the air by ozone to nitrogen dioxide. As discussed later, oxides of nitrogen then take part in further chemical reactions in the air that result in the regeneration of ozone, so the production of these gases may have not only immediate local effects but also later more distant effects.

### Carbon monoxide

Carbon monoxide is produced by the incomplete combustion of carbon-containing matter, mainly in vehicles, industrial and domestic energy production and use, and incineration. It is the most widely produced air pollutant and is particularly significant indoors, where faulty flues in domestic heating systems and escape of the gas from industrial furnaces are responsible for many deaths each year. It is also an important component of the gas phase of tobacco smoke, and this makes the greatest contribution to the blood levels of smokers and an important contribution to those of people forced to inhale side-stream smoke. In the urban environment, the highest concentrations are found in relation to heavy traffic, in still conditions and in tunnels.

### Ozone

Ozone is a natural constituent of the air, existing in equilibrium with oxygen. In the stratosphere it filters out ultraviolet light and therefore from the human point of view serves a useful function. In the lower atmosphere the naturally low concentrations are the result of photochemical reactions involving volatile organic compounds produced by plants, together with intrusions of the gas from the upper atmosphere caused by meteorological events such as thunderstorms. As an air pollutant, it is not produced directly by any human activities but arises secondarily from the action of sunlight on nitrogen dioxide and on volatile organic compounds released into the air by vehicles and industrial and domestic processes. The essential reactions are (i) the photochemical reduction of nitrogen dioxide to nitric oxide and an oxygen radical, (ii) the combination of this radical with oxygen to form ozone and (iii) the reduction of ozone by nitric oxide to reform nitrogen dioxide and oxygen. Thus, in steady-state conditions there is an equilibrium between oxygen, ozone and nitrogen dioxide. The introduction of large quantities of nitrogen dioxide or volatile organic compounds into the system

moves this equilibrium towards the greater production of ozone.

These photochemical reactions are obviously dependent on the presence and intensity of sunlight, and therefore ozone is a more important pollutant in sunnier southern than northern climates. The reactions also take time and thus ozone tends to be produced at some distance from the site of production of the primary pollutants. It is therefore likely to occur in highest concentration some miles downwind of the urban centre. Indeed, the generation of primary pollutant in cities usually causes a local fall in ozone as the gas is used up in oxidizing nitric oxide. Ozone concentrations thus tend to be highest in the countryside and suburban areas. The gas also drifts over long distances and may cause pollution episodes across national boundaries. In the UK, the highest concentrations are measured in the south and west and the lowest in Scotland (Fig. 11.6). Atmospheric photochemistry is a complex

subject and many other reactions take place simultaneously, producing such substances as aldehydes, hydrogen peroxide, peroxyacetyl nitrates and nitric acid, many of which are respiratory irritants. Low concentrations of these and many other chemicals can be found in the air. The blue haze visible over distant mountains and when looking down towards earth from an aeroplane is due to refraction of light by ultra-fine condensation particles produced by these photochemical reactions [6].

### Carcinogens

The main carcinogens that may be found in ambient air are benzene, 1,3-butadiene and several of the polycyclic aromatic hydrocarbons (PAHs) including benzo[a]pyrene, benz[a]anthracene and dibenz[a,h]anthracene; all are genotoxic carcinogens. Benzene and butadiene are produced mainly by vehicle engines, as a result of combustion

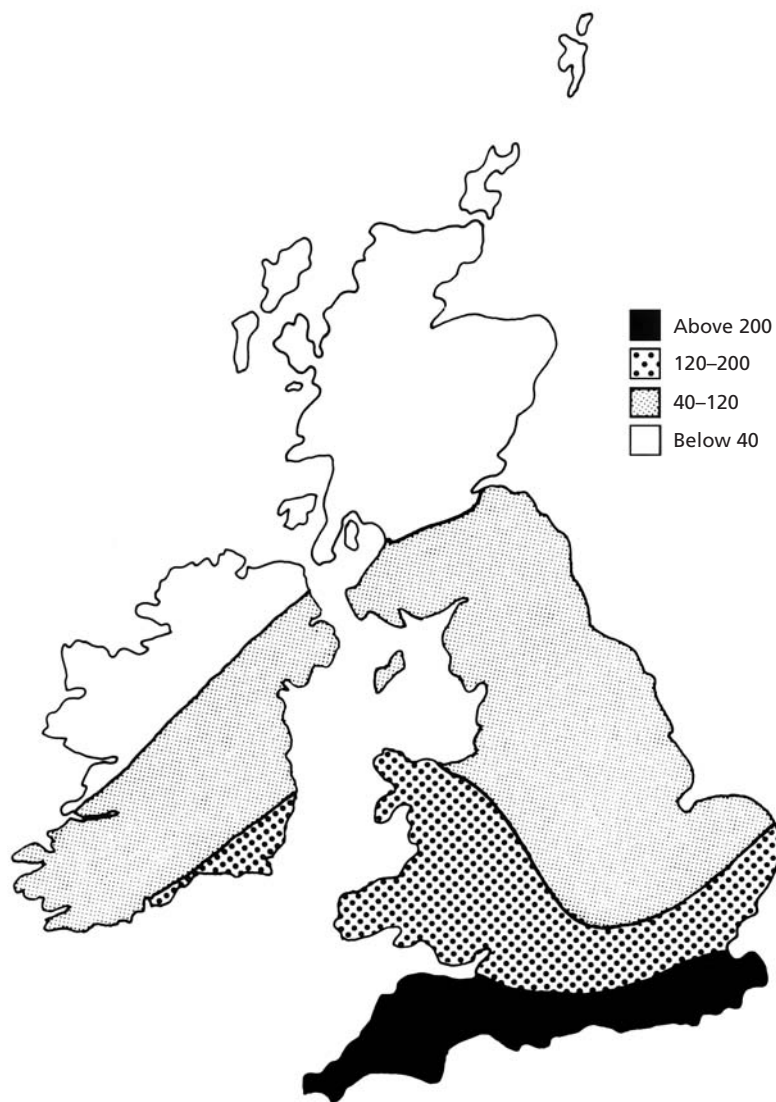

Fig. 11.6 Distribution of ozone over the UK, representing number of hours at which concentration exceeds 60 ppb. Higher concentrations occur more frequently in the sunnier south. (From Department of Health Advisory Group on the Medical Aspects of Air Pollution Episodes [5] with permission.)

of petrol, and are therefore urban pollutants. The amount of benzene produced depends more on the efficiency of the engine than on the concentration of the chemical in the original fuel, although leakage at filling stations makes a contribution to benzene concentrations in the immediate locality. PAHs are produced by coal burning and coke production, as well as by vehicles. Concentrations of these are likely to have been much higher in the days of widespread coal burning than they are today in western cities.

### Other pollutants

Many hundreds of chemicals may be detected in the air by sensitive techniques in relation to industrial and commercial activity, the cultivation and natural growth of plants and the presence of animals. A number of these assume significance when produced or released in locally high concentrations by industrial processes, and some are discussed in Chapter 54. Lead is mainly present in the air in the form of submicrometre-sized particles, derived largely from additives in petrol and locally from smelters and industrial processes. It has known neurotoxic effects, though airborne lead makes a relatively small contribution to the overall exposure of children in the UK, the main contribution being from food and from water in areas where lead pipes are still present. Many countries, including the UK, have taken steps to reduce lead levels in the urban atmosphere by selective taxation of leaded petrol. None of the other pollutants is established as a cause of health problems in the general environment and all occur in concentrations that are currently thought to be too low to constitute a significant threat to health.

### Effects of air pollution

Knowledge of the effects of air pollution comes from three sources: epidemiological studies, experimental exposures of people and animals, and *in vitro* experiments. The most useful, because they are the most realistic, are epidemiological studies, although they have the disadvantages that they often lack good information on exposures and that the exposures are usually due to a combination of pollutants. However, they are normally the only studies that can ethically assess the effects of pollution on the elderly and infirm and they do provide information that can be used in a standard setting. In some cases, epidemiological studies carried out on populations of industrial workers may be used to estimate effects on people exposed to the lower concentrations occurring in the general environment. Experimental studies on people have proved helpful in the search for no-effect thresholds with exposures to irritant gases and in investigating mechanisms of disease. They have the disadvantage that people who are already ill, for example with asthma, and who might be expected to be particularly sensitive are usually unable to

be studied, and they are often quite demanding in terms of both time and the cooperation of the experimental subjects. Animal and *in vitro* studies are best for investigating mechanisms, but are of considerably less value for obtaining information on relationships between exposure and response.

### Particles

In spite of the likely qualitative differences between particles derived from different sources, there is now strong and consistent evidence of relationships between population exposures to PM<sub>10</sub> or black smoke and risks of a number of health outcomes including mortality [7–11]. These relationships have not allowed a threshold to be defined, suggesting that rises in the concentration of particles from whatever level increase the number of people suffering ill-health. Whereas in the London smogs of the 1950s it was easily recognized that excess deaths and hospitalizations occurred, the much lower urban concentrations of particles prevailing in western cities now mean that much more subtle statistical techniques are required to detect any effect. The most important effect is an increase in the numbers of deaths. This occurs mainly in the elderly and is most marked in smokers. The cause of this overall increase is an excess of respiratory and cardiovascular deaths. There is also increasing evidence that the risk of dying from heart and lung disease and from lung cancer is increased in people living in polluted cities [12,13], although it is possible that there are confounding factors related to the social structure of the different places studied that may not have been fully taken into account. At present the evidence suggests strongly that there is an influence of air pollution in bringing forward the time of death, although the consequences in terms of loss of life-years have not yet been estimated.

Rises in concentrations of small particles have also been associated with increases in the numbers of people with asthma seeking help from their doctors or being admitted to hospital, with increased hospital admissions for respiratory disease and with increased incidence of respiratory symptoms and small falls in ventilatory function [14–16]. In some of these studies it has been difficult or impossible to differentiate the effects of particles from those of temperature or other coincident pollutants, usually sulphur dioxide, but meta-analysis has suggested strongly that particles are the most likely cause. Based on the most up-to-date data, the Department of Health in the UK has estimated the approximate consequences of particulate air pollution as an annual 8100 deaths brought forward and some 10500 extra or earlier hospital admissions for respiratory disease [17]. Calculations by the World Health Organization (WHO) of the consequences of particulate air pollution are shown in Table 11.1 [18].

The mechanisms whereby particles exert these effects

**Table 11.1** Health effects of particles.

Health effect	Rise in 24-h particle concentration (PM <sub>10</sub> ) (µg/m <sup>3</sup> )
Daily mortality	
5% increase	50
10% increase	100

10% increase	20
20% increase	40
Population fall in peak flow rate	
5%	100
10%	400

are not understood. If, as seems likely, they are true effects and not the consequences of some confounder, the explanation is likely to reside in the common properties of particulate pollution clouds, since the effects seem to be similar wherever they have been investigated. Thus detailed chemistry is unlikely to hold the explanation; rather it seems plausible that the answer lies in the fact that pollution episodes expose people to huge numbers of ultra-fine submicrometre-sized particles with a large surface area and the potential to carry toxic substances deep within the acinus. Experimental studies with such particles have shown that they may behave quite differently to larger particles, even inert substances such as titanium dioxide causing intense alveolar inflammation when inhaled by rats in a very finely divided form [19]. If typical particulate air pollution has similar effects it would be possible to explain its effects on the lungs and airways and, by invoking secondary effects through an acute-phase reaction on blood coagulation mechanisms, on cardiovascular mortality [20]. Some support for this hypothesis comes from the demonstration of free radical release, generated by a transition metal redox mechanism, from the surface of PM<sub>10</sub> and from the demonstration of higher blood viscosities in people during a European air pollution episode [21,22]. With respect to lung cancer, it is at least plausible that the presence of PAHs adsorbed on to particles deposited in the airways might be responsible for increasing risk [23].

### Sulphur dioxide

Sulphur dioxide is an irritant gas that, when inhaled in high concentration in industrial accidents, causes acute tracheobronchitis. At lower concentrations there is consid-

erable variability in responsiveness, although asthmatic individuals are generally more sensitive. In healthy volunteers, falls in ventilatory function have been recorded after inhalation of concentrations around 5000 ppb, while asthmatic individuals may respond at about 200 ppb or even lower, depending on severity [24]. The response is almost immediate, suggesting a neural reflex mechanism, and seems not to become worse with continued exposure. The severity of the response is affected by exercise and thus seems to depend on the amount of gas inhaled during the initial exposure. There is some evidence that people living in areas where there is long-term pollution with sulphur dioxide have an increased risk of exacerbations of chronic lung disease and decrement in lung function. While these studies have often been confounded by concurrent exposures to particles, there is now evidence from parts of Europe where sulphur dioxide has remained elevated as particle concentrations have fallen that long-term exposures to annual average concentrations around 20 ppb may be associated with such adverse health effects.

### Oxides of nitrogen

As stated above, most combustion sources produce nitric oxide, which is rapidly oxidized to nitrogen dioxide. The latter gas is a relatively insoluble pulmonary irritant that, when inhaled in high concentrations (as in exposure in silos or chemical accidents), causes delayed pulmonary oedema and sometimes bronchiolitis obliterans; these effects are described in Chapter 54. Nitrogen dioxide shares with carbon monoxide the characteristic of often reaching higher concentrations indoors than out, since it is a product of gas combustion. Experimental exposure of volunteers in chambers has shown that both normal subjects and asthmatic patients are relatively resistant to nitrogen dioxide, small and inconsistent changes in airway reactivity and resistance occurring at concentrations between 1000 and 4000 ppb [25]. These concentrations far exceed those found in even severe urban pollution episodes, maximum hourly concentrations in the UK usually being below 250 ppb. Epidemiological studies have suggested that there is an increased risk of respiratory illness in children and women living in houses with gas cookers, where the concentrations may rise to 500 ppb or higher [26,27]. The highest background urban concentration recorded in London, 423 ppb in December 1991, was associated with a small rise in overall mortality and hospitalization for respiratory disease among the over 65 years age group but no measurable effect in younger people [28]. These effects were most likely to have been due to a concomitant rise in particles. On balance, it seems unlikely that ambient levels of nitrogen dioxide have a significant direct effect on public health, although they are an important contributor to the formation of ozone.

## Carbon monoxide

Carbon monoxide is a metabolic poison, blocking intracellular respiration by binding to cytochrome oxidase and myoglobin and interfering with red cell transport of oxygen by the formation of carboxyhaemoglobin. It is the most dangerous of all the pollutant gases, regularly causing deaths and long-term brain damage in people exposed accidentally and in self-poisoning episodes. It has been suggested that it may also contribute to acute cardiovascular episodes such as heart attack and angina by reducing the oxygen-carrying capacity of the blood in people with compromised circulations. The main sources are petrol engines, which produce some 6 million t annually in the UK, and domestic use of fuel, which produces some 300 000 t annually.

The effects of carbon monoxide on health probably depend mainly on the blood carboxyhaemoglobin concentration, and no effects have been recorded below a concentration of 2.5% [29]. Whether this level is attained depends on inhaled concentrations, level of activity and duration of exposure. The blood and the surrounding air reach an equilibrium, and moving from a higher to a lower concentration may result in excretion rather than further uptake of the gas. Thus a regular smoker who might have a carboxyhaemoglobin of 3.5% is, in most circumstances, contributing to the ambient carbon monoxide rather than taking it up. During normal activities, it may be calculated that exposures of greater than 10 ppm for 8 h or 25 ppm for 1 h are required to bring the carboxyhaemoglobin concentrations of a non-smoker up to 2.5%. Ambient urban concentrations in the UK only rarely exceed these figures in places where people are likely to be exposed for the appropriate periods. Carboxyhaemoglobin concentrations of around 2–2.5% have been recorded in non-smoking traffic police and people working in underground garages.

In spite of these observations, epidemiological studies have shown associations between ambient carbon monoxide concentrations, hospital admissions and mortality, especially from cardiovascular diseases, in both North America and Europe [16,30,31]. It seems plausible that even quite small rises in ambient carbon monoxide concentrations could influence cardiovascular function in very vulnerable individuals with coronary arterial disease.

## Ozone

Because ozone is produced by atmospheric photochemical reactions, it is a problem in sunnier climates. In the UK concentrations are highest in the south and decline progressively towards the north. Since it is generated by a relatively slow reaction, ozone concentrations increase downwind of the urban areas in which the primary pollutants are produced, making it a mainly rural pollutant in

the UK. Experimental studies have shown it to be a pulmonary irritant, causing increases in bronchial resistance and reactivity in relation to the dose inhaled. This means that exercise, by increasing the ventilatory volumes, increases the effects of a given ambient concentration. The lowest concentration at which effects have been demonstrated is around 80 ppb over several hours in healthy individuals [5]. There is no convincing evidence that people with asthma as a class are more sensitive, but it would be expected that the effects of further airway constriction in someone who already has airflow obstruction would be disproportionately greater, since resistance to flow is inversely proportional to the fourth power of the radius.

Epidemiological studies have in general supported the concept that ozone above concentrations of around 100 ppb may have acute effects on the ventilatory capacity of children. It has been suggested that airway inflammation induced by ozone may increase the likelihood of an individual becoming sensitized to ambient allergen, and there is experimental evidence that ozone inhalation decreases the allergen concentration at which sensitized people react [32]. Spring and summer upper respiratory symptoms are very common in rural areas [33] and it is likely that ozone plays some part in the aetiology of these. In the UK, the ambient concentrations of ozone may reach 150 ppb or more in the south on hot summer days but rarely reach 100 ppb in Scotland.

## Carcinogens

The evidence that the concentrations of carcinogens present in the ambient urban air are responsible for causing bronchial cancer has been mentioned above with respect to particles. Benzene and 1,3-butadiene are probable causes of leukaemia and lymphoma in occupational settings, but at exposure concentrations three or four orders of magnitude higher than those found in cities. It seems unlikely that they will be shown to contribute to the incidence of these conditions as a result of current ambient concentrations in the West.

## Combinations of pollutants

In the normal environment individuals are always exposed to mixtures of pollutants. Typically, in winter pollution episodes, particles and sulphur dioxide or nitrogen dioxide combine; indeed the sulphur dioxide and nitrogen dioxide exist in equilibrium with sulphate and nitrate radicals, which are important contributors to the particulate cloud. It is usually not possible to distinguish the effects of these pollutants in any one study and it is possible that the harmful effects of particles described above are in part due to their acidic nature. Relatively little work has been done on combinations of irritant

pollutants, although it is reasonable to assume that their effects would be additive.

### Indoor air pollution

The main sources of indoor air pollution are cigarette smoke, gas-burning cookers and heaters, paints and treated building materials such as wall panels. Cigarette smoke, as discussed previously, contains a wide variety of carcinogenic and irritant substances. It is the main personal source of benzene exposure. Gas-burning devices and other open-flame burners, if not fitted with an effective flue, may produce carbon monoxide, far and away the most important indoor air pollutant since it is responsible for regular loss of life in houses. Gas cookers are also the major source of nitrogen dioxide; this gas often reaches higher concentrations indoors than out, averaging around  $50\mu\text{g}/\text{m}^3$  over several days when measured in houses with gas cooking and reaching peaks of up to  $1000\mu\text{g}/\text{m}^3$  over 1 h during cooking. In spite of this, the evidence that it causes harm remains equivocal [34] and is consistent with the experimental observations quoted in the section on oxides of nitrogen (see p. 330). Some studies have shown that women and children living in houses with gas cookers suffer more respiratory illnesses than those in houses with other types of cookers [26,27], although there is little consistency in the evidence with respect to adverse effects on lung function. However, there is some evidence that exposure to relatively high concentrations ( $400\text{ ppb}$  for 1 h) increases the subsequent response to challenge to house-dust mite antigen and this may be of some relevance to the health of children [35].

Paints, household cleaning materials and other chemicals are sources of volatile organic compounds, which make a contribution to the overall mass of airborne substances available for the photochemical reactions that lead to the formation of ozone. They probably also contribute to the irritancy of indoor air. Formaldehyde, which is used for treating building materials, may be detected in houses in higher concentrations than outdoors. It is found particularly in newer houses and tends to reach higher concentrations in summer than in winter. In the UK, concentrations have varied between 1 and  $200\mu\text{g}/\text{m}^3$ . The WHO has recommended a standard of  $100\mu\text{g}/\text{m}^3$  over 30 min.

While not strictly pollution, mention should be made of the natural inhabitants of houses that may be responsible for illness. House-dust mites are ubiquitous in beds, carpets and soft furnishings, and their faeces are the source of the major sensitizing antigens in most temperate climates. They reproduce best in warm and damp conditions. Fungi are also found in houses, and in rare circumstances may grow in such profusion as to cause allergic alveolitis. These organisms are discussed further in Chapters 21 and 34.

### Advising patients about air pollution

Many patients with asthma notice changes in their condition with changes in the weather, some commenting that it is the change rather than a particular type of weather that affects them. This does not seem to relate clearly to episodes of pollution, although in epidemiological studies of such episodes it has often been shown that such people make additional demands on health services because of attacks. A number of patients with asthma notice that their breathing gets worse when exposed to traffic fumes or when they visit polluted cities, such as Athens. The most consistent evidence associates these events with a rise in the concentration of small particles in the air, the same type of pollution associated with excess numbers of deaths among older people from cardiorespiratory disease. Such episodes may be predicted with reasonable accuracy the day before from knowledge of the weather forecast and likely traffic volumes, and it would seem reasonable for the authorities to issue a warning. However, it is far from clear what action, if any, might be taken to prevent these adverse effects. With respect to asthma, the sensible advice in the light of present knowledge might be for patients who have been affected by these conditions in the past to avoid places where traffic is heavy and, if they are seriously affected, to keep indoors and keep warm. In the author's view it is not desirable to issue general advice to all asthmatic individuals to restrict their activities, since there is no evidence that this is either necessary or beneficial. In particular, there is no case for restricting the activities of children unless they have quite severe disease. However, it is sensible to advise such people that they may need to increase the doses of their inhalers. Patients with asthma or chronic lung disease contemplating foreign travel should be warned to avoid notorious pollution blackspots, such as Athens, Cairo, Mexico City, Bangkok, Delhi and Calcutta.

There is at present no clear indication as to what measures patients with chronic heart and lung disease might take to prevent a possible increased risk of death; however, if small particles are responsible, as seems likely, avoidance of areas of heavy traffic pollution would seem sensible. There are almost certainly benefits to staying indoors for such people, since indoor particle concentrations tend to be somewhat lower than those outside (except when influenced by cooking or smoking) [36] and the temperature, another factor associated with increased risk, is usually higher.

In the UK the main risks occur during cold still conditions in winter, when traffic-generated fumes are poorly dispersed and lie in a pall over the towns and cities. Summer pollution episodes normally involve ozone, which sometimes reaches concentrations at which some sensitive people might notice symptoms. When such an episode is predicted, it might be reasonable to advise

people with asthma that they may develop bronchial symptoms if they take prolonged exercise, and that they should be prepared to take extra doses of their usual treatment.

## Control of air pollution

Air pollution is perceived by the public and some governments as a serious threat to public health. It also has important economic effects on the environment, on trees, crops and buildings. Health benefits have been shown to occur when pollution is reduced, as has happened in the UK with the control of coal burning in cities. It is not clear how much further improvements in air quality will benefit health in the UK, but evidence shows that there is scope for a reduction in costs associated with the management of acute episodes of respiratory disease and possibly for a reduction in the number of deaths among older people with heart or lung disease. There is little question that substantial benefits to health would accrue with pollution control in those cities in other parts of the world where concentrations approach or exceed those that existed in London in the 1950s.

The control of air pollution is a matter for government policy, taking account of the costs and likely benefits. It requires strategic action to reduce the emissions at source. Thus, halting of the rise in personal ownership of cars and transfer of heavy transport from road to rail, restrictions to the access of cars to city centres, and elimination of vehicles exceeding emission limits are all actions that governments will contemplate. Shorter-term measures include introduction of emission controls, such as catalytic converters on petrol cars and filtration systems on diesels, and tighter enforcement of regulations reducing exhaust emissions. Fiscal measures may be useful; the differential tax on leaded petrol in the UK has reduced lead emissions substantially, and a similar measure might be contemplated to restrict the growth of the private diesel car market, since diesel is now the main source of particles.

Any strategy to control air pollution needs to be audited by appropriate air monitoring. In the UK, the Department of the Environment has a series of monitoring stations to

**Table 11.2** UK air quality standards.

measure a wide range of pollutants. These allow long-term trends to be followed and therefore the achievement of targets to be monitored. The UK Government, along with other organizations such as the European Community and the WHO, is considering a series of air quality standards or guidelines at which health effects are thought to be absent or minimal and against which progress in control of air pollution can be measured. The current UK standards are given in Table 11.2. These figures should not be confused with those levels at which public health warnings may be given, since in general they represent a 'no effects' target, while warnings, if given, usually represent a level at which adverse health effects have been demonstrated.

Ultimately, the control of air pollution depends on sufficient public concern stimulating politicians to propose remedies that are broadly acceptable to the public and that do not entail an unacceptable cost. The complexity of the issue may be recognized by weighing the value one places on one's car for personal transport against the nuisance of pollution and the cost of increased local or national tax to pay for better public transport systems and the likely introduction of increased costs of fuel to reduce energy usage. In some countries, such as western Germany, strategic action and investment has produced great benefits. In others, such as the east of that country, complete inaction has resulted in environmental disaster. In every developed country there is the threat, indeed the likelihood, that the gains of the past 30 years will be lost if a comprehensive transport policy is not part of the government's programme.

# ACUTE UPPER RESPIRATORY TRACT INFECTION

DOUGLAS SEATON

Upper respiratory tract infections are by far the most common medical complaints worldwide and in the UK account for half the time lost from work through acute illness. They are for the most part self-limiting but nevertheless place a considerable burden of work on general practitioners and other primary care workers and have an important economic impact on communities [1,2]. Such illness may be complicated by lower respiratory tract infection, a fact of global importance to millions of children, particularly in developing countries where lack of antimicrobial therapy results in considerable mortality [3,4]. In adults too there is little doubt that upper respiratory tract infection is complicated by more serious lower respiratory tract disease; thus coryzal symptoms of viral origin frequently precede the onset of pneumococcal pneumonia, which like the common cold shows an increased incidence in the winter months [5,6]. The season of respiratory tract virus infections is also associated with an increased frequency of asthma attacks and exacerbations of other established lower respiratory tract disease, such as chronic bronchitis and cystic fibrosis [7,8]. Upper respiratory tract infections may also be problematical in patients who are immunocompromised as a result of various conditions, including neutropenia, immunosuppression following transplantation and AIDS.

## Common cold (acute coryza, nasopharyngitis)

This term is applied to a self-limiting illness, characteristically of short duration and typified by nasal discharge, sneezing and a sore throat. These 'catarrhal' symptoms result from infection of the upper respiratory tract by one or more of a large number of different viruses. Although the illness produced by this nasopharyngitis is generally mild, its importance stems from the fact that:

1 it is the commonest human disease and is one of the most common reasons for patients seeking medical advice;

2 it is a major cause of absenteeism from school in children and from the workplace in adults;

3 it may be complicated in susceptible individuals by bacterial infection and by exacerbations of pre-existing respiratory disease.

## Causative organisms

'Catching a cold' has for many years been thought to result from the spread of infection. Early observations of the contagious nature of the 'coryzal syndrome' led to the demonstration over 80 years ago that bacteria-free filtrates of the nasal secretions of cold sufferers produced a similar illness when inoculated intranasally into healthy volunteers [9]. Further animal and human work led to the conclusion that the filterable agents were viral [10] and the isolation of specific cold-causing viruses followed in the 1950s, first with the rhinoviruses [11,12].

The *Rhinovirus* genus, which belongs to the family Picornaviridae (*pico-* denotes small size and *-rna-* their type of genome), contains over 100 antigenically distinct rhinovirus species and is the largest genus known to cause common cold symptoms, accounting for about 30% of cases.

The next most common group of viruses, causing up to 15% of 'colds', is the *Coronavirus* genus. This contains many species that are pathogenic to humans and is the only member of the family Coronaviridae, so called because of the crown-like appearance of these viruses under electron microscopy.

Other viruses that have been identified as causing 'colds' include the parainfluenza viruses and the respiratory syncytial virus (RSV), both of which are species of virus belonging to different genera but the same Paramyxoviridae family. As well as causing lower respiratory tract infections in infants and small children, RSV and parainfluenza viruses may be responsible for up to 15% of 'colds' in adults.

There are a number of species of human adenovirus that may cause coryzal symptoms. These organisms belong

to the Adenoviridae family. They are the only DNA-containing viruses to cause the common cold and account for about 5% of these infections. Some human adenovirus serotypes cause diverse disease, including conjunctivitis, meningitis and gastroenteritis as well as pneumonia.

The influenza viruses may produce common cold-like symptoms but are often associated with a more prostrating infection, as described in a later section. Like parainfluenza and RSV, influenza viruses are loosely termed 'myxoviruses', belonging as they do to the Orthomyxoviridae family.

The *Enterovirus* genus, which also belongs to the Picornaviridae, includes some Coxsackie [13] and echovirus species that may produce upper respiratory symptoms, as indeed may polio virus infection. Some exanthematous viruses such as chickenpox (varicella), rubella and measles may also produce coryzal symptoms.

Since the isolation of the coronaviruses in the 1960s [14,15], no new common cold viruses have been discovered. Despite this, a causative organism cannot be found in over 30% of cases and undiscovered common cold viruses are therefore presumed to exist. Most of the common cold viruses undergo frequent mutations so that it has not been possible to develop an effective vaccine.

### Pathology

Pathological changes in the common cold result from the invasion of the nasopharyngeal mucosa by 'cold viruses'. These are not usually present in asymptomatic individuals [16], although subclinical infection may occur and viral carriage is sometimes prolonged in children [17]. The infecting virus attaches to and penetrates the respiratory columnar epithelial cell by a variety of mechanisms, before replicating and being shed so that neighbouring cells become infected. There are no specific histological changes but characteristic findings include mucosal oedema with shedding of columnar epithelial cells, which are found within the proteinaceous nasal discharge. These shed cells show degenerative changes and contain both viral antigenic material and nuclear inclusion bodies [18,19]. The shedding of epithelial cells and virus is usually completed within a few days [18,20,21] and although mucosal damage is only slight in the majority of cases [22], cellular recovery by regeneration of epithelial cells from the deeper layers takes about 2 weeks [23]. Neither neutrophils nor mast cells feature prominently in the mucosa or submucosa in this process, although the inflammatory picture may be changed in cases where the normal nasopharyngeal flora is altered as a result of secondary bacterial infection. One ultrastructural study showed damage to epithelium with loss of cilia peaking 1 week after the onset of infection, complete repair having been achieved by 3 weeks [24].

### Epidemiology

Upper respiratory tract viruses are distributed worldwide [25], antibodies to them being commonly detectable in the serum of subjects living in both temperate and tropical zones [25,26]. These antibodies are found with increasing frequency and variety throughout childhood and adolescence [27,28]. Infants are protected by maternal antibodies for 2–3 months [22], after which a child contracts six to eight colds per year [29,30]. Children tend to act as a reservoir of infection in the community [31,32], both in the classroom [33] and at home [29,34], where the presence of a child of school age doubles the chance of common cold infections in parents and preschool siblings [35]. The attack rate diminishes to two to four per year in adulthood as a result of a gradual build-up of immunity [29,30], subjects aged 40 years and over being less susceptible than those aged less than 30 years. Despite the acquisition of immunity, the existence of very large numbers of strains of common cold virus results in sporadic infection throughout life except in small very isolated communities where protection from exposure may occur.

The incidence of colds in temperate climates is seasonal, increasing in the autumn and remaining at a high level throughout the winter months before declining to a low level in the summer [29,30,36]. The winter peak may be a consequence of increased environmental crowding at this time of the year rather than the cold temperature *per se*, and the deliberate chilling of volunteers has not been shown to increase attack rates.

Although it seems logical that colds should be spread from person to person by droplet infection, direct contact with infected secretions may also be important for some viruses. Rhinoviruses are shed heavily in nasal secretions and, in experimental infection, the peak viral titres in such secretions occur from the second to the fourth day, coinciding with the time of maximum communicability. Although in human infection rhinovirus-containing nasal secretions may be passed from hand to hand more easily than by air, thence transmitting infection to the nasal mucosa or conjunctivae of the contact [37], it seems more likely that infection is more easily spread, as was traditionally thought, by 'coughs and sneezes' [38]. It is possible that some other cold viruses may also be more easily spread by droplet transmission [39]. There is some evidence to suggest that psychological stress or 'feeling run down' may increase an individual's susceptibility to colds [40].

### Clinical features

The incubation period from exposure to the onset of illness is a day or two. The symptoms of the common cold are only too familiar to all of us as a result of personal experience. There is a feeling of malaise and tiredness, coupled

with mild to moderate nasal obstruction, rhinorrhoea and sneezing, with dryness or soreness of the throat, slight aching in the musculature and often a feeling of irritation about the eyes that usually stops short of clinically obvious conjunctivitis. There may be headache. A cough may occur either as a result of postnasal discharge or because of more distal respiratory tract involvement by the virus [41,42]. These symptoms may combine to act as a moderate disincentive to get out of bed in the morning but, depending on both the severity of the infection and the individual's motivation, need not necessarily prevent a day's work. Such is the usual pattern with rhinovirus and coronavirus infection. The occurrence of painful red eyes with a sore throat and coryzal symptoms is suggestive of adenovirus infection ('pharyngoconjunctival fever'), whereas a more prostrating illness with a fever raises the possibility of a myxovirus infection such as influenza.

There are no specific physical signs. Nasal obstruction, a dripping nose, a cough and sneezing may be obvious, as is conjunctivitis in some patients with enterovirus or adenovirus infection. A fever is a more frequent feature in children than in adults, in whom it is only low grade, if present at all. Examination of the chest in otherwise healthy individuals reveals no physical signs.

The full clinical features of the common cold syndrome usually develop within 24 h and are somewhat variable in their progression. Thus improvement often begins after the second or third day, although recovery may take from a few more days to 2 weeks, provided that no complicating features arise. The upper respiratory tract symptoms of colds usually bear no hallmark of the particular virus responsible and fortunately ignorance in this respect is of no practical importance.

About 0.5% of common colds have been found to be complicated by bacterial sinusitis and 2% by otitis media [29].

## Diagnosis

Subjects with mild and self-limiting colds frequently make their own diagnosis without 'bothering the doctor'. More protracted symptoms may be due to allergic rhinitis, in which case a painstaking history may identify either a seasonal pattern or a relationship to exposure to a consistent antigenic source. The recurrent or chronic nature of such symptoms distinguishes allergic rhinitis and perennial non-allergic (vasomotor) rhinitis from the common cold and inspection of the nasal mucosa may reveal polyps [43]. Visible inflammation of the pharynx, with a particularly red throat, raises the possibility of adenovirus infection or of causative agents other than those responsible for the common cold. These other causes of sore throat (discussed in the section on pharyngitis; see pp. 338–340) include streptococcal sore throat and infectious mononucleosis.

Childhood exanthematous infection will become obvious with the later development of a characteristic rash.

## Serological tests

In epidemiological work, serological evidence of adenovirus infection or myxovirus infection by RSV, influenza and parainfluenza virus infection may be obtained by the submission of serum obtained at the onset of the illness and 2–3 weeks later. A fourfold or greater rise in the titre of antibodies to the virus concerned implies recent infection. Such is the mild and self-limiting nature of common colds that information of this sort is unnecessary and is seldom sought in ordinary clinical practice. Indeed, where rhinoviruses are concerned it is unavailable because of the great multiplicity of antigenic strains that exist.

Various methods for detecting viral antibodies are available and these include neutralization, complement fixation and haemagglutination inhibition tests. Neutralizing antibodies may persist for prolonged periods and need not indicate recent infection, merely previous exposure. Complement fixation tests, although less sensitive, are more widely available because the antigens are easily prepared and the results more rapidly obtained. Haemagglutination inhibition tests are used to identify cultures infected with influenza and parainfluenza viruses and probably detect similar antibodies to those identified by neutralization tests. Rapid direct fluorescent antibody techniques or enzyme-linked immunosorbent assay (ELISA) are available for the detection of influenza A and B viruses, parainfluenza viruses, adenoviruses and RSV in nasopharyngeal material; washes or aspirates have a higher yield than swabs, which contain fewer columnar epithelial cells than liquid specimens.

## Viral culture

Although many respiratory viruses may be isolated in cell culture, such methods are both unnecessary and unavailable in routine clinical practice. Where investigative work demands the proper identification of respiratory viruses, close cooperation between the researcher and the virologist is essential. As the shedding of viruses may occur for only a short time, specimens should be collected early. These specimens usually take the form of nasal and pharyngeal washings or swabs, although faeces should be obtained where evidence of enterovirus infection (such as Coxsackie or echovirus) is sought. The tips of swabs are placed in an appropriate transport medium and are conveyed to the laboratory with as little delay as possible, some viruses such as RSV and parainfluenza being particularly labile. Many different tissue culture systems have been described and are in use. Rhinoviruses can be grown in human embryonic lung cells and myxoviruses and

paramyxoviruses in rhesus monkey kidney cells. Hep2 cells, originally derived from malignant tissues, support the growth of RSV. Cell culture of coronaviruses is seldom possible. The presence of a virus in tissue culture may be indicated by a cytopathic effect, by a modification of cell growth, by haemadsorption tests or by so-called 'interference', i.e. the prevention of the cell line from supporting the growth of a second virus.

### Treatment

Despite a plethora of over-the-counter remedies, no medication has been convincingly shown to cure the common cold and treatment can be only symptomatic. It has been noted that 'if common colds are left alone they clear over the course of a week, whereas if treated vigorously they disappear within seven days'. This epigram has been borne out by a relatively recent randomized, double-blind, placebo-controlled trial to assess the efficacy of the capsid-binding antipicornaviral agent pirodavis delivered by intranasal spray six times daily. This agent had been previously shown to be effective in preventing experimental colds caused by rhinoviruses [44]; when used to treat subjects with naturally occurring rhinovirus colds, the median duration of symptoms in both the active treatment and placebo group was indeed 7 days, although viral shedding was significantly reduced in the pirodavis-treated group [45].

Among the symptomatic remedies, topical nasal decongestants have their effects by causing vasoconstriction [46]. The most common of these are drops or sprays containing weak solutions of ephedrine, phenylephrine or imidazoles. Although these produce immediate relief, this may be followed by rebound nasal congestion requiring further dosage and the nasal mucous membrane may be damaged if such cyclical usage continues for more than 4 or 5 days [47], with the potential for delayed mucosal healing. Other agents that may afford symptomatic relief include an atropine-like ipratropium nasal spray, which has the effect of reducing nasal secretions [48], and inhalations of menthol. Systemic nasal decongestants are of doubtful value. Viral sore throat does not benefit from local antiseptic treatments but may be relieved by warm saline or soluble aspirin gargles. Cough suppressants containing substances such as codeine are commonly prescribed but are of doubtful benefit and, as an alternative, simple linctus BP (British Pharmacopoeia) is a harmless preparation that may have some useful soothing effect. Aspirin may be used as an antipyretic and for myalgia but should not be prescribed in children because of the remote chance of causing Reye's syndrome [49], paracetamol being a suitable alternative. Bland ointments or creams are useful in preventing cutaneous excoriation about the nostrils and lips. The breathing of warmed humidified air has been shown to produce symptomatic relief [50]. A gener-

ous tot of Scotch whisky adulterated with honey and hot water, to be taken before bedtime, is probably as effective as any of the foregoing!

Antibiotics are of no value in treating the *uncomplicated* cold but are sometimes prescribed prophylactically to patients with chronic lower respiratory tract disease at the onset of upper respiratory tract symptoms in order to prevent an exacerbation due to secondary bacterial infection. Large doses of vitamin C, although sometimes taken in ritual manner to prevent colds, have unfortunately not been demonstrated to be effective in preventing experimental rhinovirus infection [51]. There is at present no prospect of an effective vaccine in view of the enormous multiplicity of serologically distinct causative viruses. Apart from pirodavis, other antiviral agents such as interferons, applied intranasally, have been investigated [52] and have shown some promise as a short-term prophylactic for rhinovirus colds [53], but have not come into general use because of expense and tiresome side-effects such as local mucosal dryness and bleeding.

Patients who are susceptible to lower respiratory tract infections do not usually have to be reminded to avoid contact with cold sufferers whenever this is possible, and simple measures such as hand-washing may help to prevent viral spread.

### Complications

A small proportion of common colds are complicated by bacterial infection and may require antibiotic treatment. The mechanisms may involve direct viral invasion, disruption of mucosal surfaces and damage to the mucociliary escalator. This mucosal injury produces local oedema, which in turn has the effect of blocking those channels or passages that normally open into the nasopharynx. These include the ostia of the frontal, maxillary and sphenoidal sinuses, the ethmoidal cells, the eustachian tubes and the nasolacrimal ducts. Such obstruction creates conditions favourable to the development of acute sinusitis and otitis media [29], as well as the symptom of watery eyes. Extension of infection caudally may predispose to tracheobronchitis and in patients with asthma may well provoke wheezing. There are occasionally reports of non-bacterial pneumonia occurring in otherwise healthy adults in association with infection by coronaviruses, parainfluenza viruses and Coxsackie viruses.

### Acute pharyngitis and tonsillitis

Of cases of acute pharyngotonsillitis 80–90% are caused by viruses, particularly adenoviruses, although rhinoviruses, coronaviruses and the other viral causes of common cold symptoms mentioned above may also be responsible. RSV infection usually causes only a mild pharyngitis in adults, although it may cause severe bronchiolitis in infants, often

in epidemic form from late autumn to early spring. Group A  $\beta$ -haemolytic streptococcal (*Streptococcus pyogenes*) infection may produce a more severe bacterial illness, this organism having a predilection for the tonsils. Such infections are commonest in children but may also occur in adolescence and adult life. *Strep. pneumoniae* and *Haemophilus influenzae* may be secondary invaders. Less commonly, group C  $\beta$ -haemolytic streptococci may be implicated, as may the 'atypical' organisms *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*. Febrile pharyngitis is a feature of primary human immunodeficiency virus (HIV) infection. Sexually transmitted pharyngitis may be caused by *Neisseria gonorrhoeae* and *Treponema pallidum*.

### Clinical features

Symptoms and signs are very variable. Most patients experience a slight sore throat, often of brief duration. Acute pharyngitis caused by some adenovirus serotypes may be associated with fever, cervical lymphadenitis and conjunctivitis, a syndrome that may occur in epidemic form in children in the summer months, so-called pharyngoconjunctival fever. When Coxsackie A virus causes a sore throat it is accompanied by small vesicles that appear on the palate and ulcerate. The illness, sometimes known as the herpangina syndrome, is short-lived and may be accompanied by malaise and fever. Primary infection by herpes simplex virus may cause a somewhat similar appearance. A 'mononucleosis syndrome' similar to that caused by Epstein-Barr virus (see below) may be caused by cytomegalovirus infection or HIV infection and should be suspected when there is a persistent and more severe sore throat, often accompanied by malaise, sometimes with lymphadenopathy, splenomegaly and an atypical lymphocytosis on the blood film. Primary HIV infection may also cause a 'mononucleosis syndrome', accompanied by malaise, fever and sore throat, sometimes with lymphadenopathy and a maculopapular rash.

A few patients with acute pharyngitis or tonsillitis experience a more severe febrile illness with general symptoms of systemic toxicity and dysphagia in which there is pharyngotonsillar oedema, hyperaemia and cervical lymphadenopathy. A white pharyngeal or tonsillar exudate may form in severe cases, such as those caused by group A  $\beta$ -haemolytic streptococci.

Other less usual causes of membranous pharyngitis are considered below.

### Diphtheria

Diphtheria caused by infection with *Corynebacterium diphtheriae* and occurring in unvaccinated populations exhibits prominent systemic symptoms: there is a greyish pharyn-

geal membrane with little surrounding hyperaemia; cervical lymph nodes may be much enlarged, producing a 'bull neck', not to be confused with mumps; the pulse rate is increased disproportionately to the fever, which is low grade. The diagnosis depends upon a high index of clinical suspicion, and prompt hospital treatment with diphtheria antitoxin may be life-saving. Subsequent laboratory confirmation of the diagnosis follows a throat swab culture.

### Vincent's angina

Vincent's angina (anaerobic pharyngitis or 'trench mouth') is a membranous pharyngotonsillitis that may arise in a patient with poor oral hygiene as a result of anaerobic infection by the Gram-negative spirochaete *Borrelia vincenti* and other anaerobic fusobacteria. The diagnosis is supported by microscopic examination of throat swab smears of the exudate, stained to show fusobacteria and spirochetes. Treatment is with penicillin.

### Infectious mononucleosis

Infectious mononucleosis is associated with pharyngitis in 80% of cases, sometimes with membrane formation. Coryzal symptoms are absent and the presence of posterior cervical lymph node enlargement and splenomegaly may be of diagnostic assistance. Tonsillar enlargement is common; very rarely, fatal upper airway obstruction may occur [54]. The diagnosis of infectious mononucleosis is confirmed by the presence of atypical mononuclear cells in the blood film and positive tests for heterophile antibodies (Paul-Bunnell test). When the Paul-Bunnell test is negative, Epstein-Barr virus-specific antibodies may be detected in the serum.

### Oral thrush (candidiasis)

Oral thrush, which may produce a sore mouth and throat, is caused by *Candida albicans* infection and usually occurs in patients after they have received broad-spectrum antibiotics or immunosuppressives, including corticosteroids whether systemic or inhaled. It is characterized by the presence of typical white plaques on the gums, tongue, palate and fauces. Diagnosis is based on the clinical findings and treatment is with nystatin or amphotericin locally. More persistent or severe infection may be treated with an oral azole such as fluconazole. Underlying blood dyscrasias such as leukaemia or other causes of a compromised immune system should be considered in any persistent or severe pharyngitis. *C. albicans* is a frequent pathogen in leukaemic patients and may also cause infection in transplant recipients and patients with AIDS. Serious invasive infection in this group may require treatment with amphotericin.

## Treatment

Treatment is symptomatic in a case of mild uncomplicated pharyngotonsillitis and the vast majority of such infections resolve spontaneously. Antimicrobial therapy is usually reserved for more severe infections, in which case haemolytic streptococci are usually responsible. These can be cultured from a throat swab and the result should be available within 24 h. Commercially produced kits now exist for detecting group A streptococcal antigen from throat swabs within 1 h. Their specificity is high (>98%), so that a positive result dispenses with the need for culture. Sensitivity is less satisfactory (80–90%), so that if antigen is not detected culture should still be performed [55]. Oral penicillin is the antibiotic of choice, a macrolide being used if the patient has a history of allergy to the former drug. Ampicillin/amoxicillin (amoxycillin) should be avoided for fear of causing a rash in infectious mononucleosis. Penicillin is also used to treat Vincent's angina. It is usual practice to treat diphtheria with intravenous antitoxin, a measure that has been shown to reduce mortality, further toxin formation being reduced by eradication of the organisms with penicillin or a macrolide.

## Complications

Complications of pharyngotonsillitis are rare and are generally associated with bacterial rather than viral infections. They include peritonsillar abscess (quinsy), which is treated with benzylpenicillin and sometimes requires surgical drainage; cervical abscess, similarly treated with penicillin and drainage; and retropharyngeal abscess, which may produce respiratory difficulties and which is demonstrable on a lateral radiograph of the neck and on CT, as is the laterally extending parapharyngeal abscess. In addition to antibiotic treatment, these complications also require surgical drainage, both to relieve symptoms and to prevent extension of infection down the fascial planes to the mediastinum. Rheumatic fever and acute glomerulonephritis are nowadays unusual complications of streptococcal pharyngotonsillitis in Western practice.

## Acute supraglottitis (epiglottitis)

This is a febrile illness in which acute infection is mainly localized to the epiglottis and surrounding supraglottic tissues, which become cellulosic, assuming a swollen 'cherry-red' appearance. It is primarily caused by *H. influenzae* type b, although streptococci and staphylococci have occasionally been implicated. Although rare, prompt diagnosis is essential as it may cause a fulminant and potentially fatal illness in a previously healthy patient, the upper airway becoming critically obstructed by gross soft tissue swelling within a few hours. The infection produces a sore throat, hoarseness and dysphagia followed by

inspiratory stridor with the onset of supraglottic obstruction. A high index of suspicion is needed as deaths may occur when patients presenting with a rapidly developing severe sore throat are sent home from emergency departments before the onset of obstructive symptoms [56]. Although the peak incidence of acute epiglottitis is between 2 and 4 years of age, it is emphasized that this condition is also an important illness in adults, in whom a mortality rate of 7% has been recorded [57]. Attempts to examine the throat by depressing the tongue may result in fatal upper airway obstruction in children but in adults indirect or flexible laryngoscopy is safe [57,58]. In childhood the patient is typically feverish and unwell, developing breathing difficulties within a few hours, tending to sit upright, drooling from the open mouth because of an inability to swallow and breathing in a tentative and cautious manner with muffled inspiratory stridor and absence of cough.

The immediate treatment in all cases is to secure the airway by endotracheal intubation in preference to tracheostomy, and the 'at-risk' patient should not be left unattended by responsible medical personnel until this has been achieved. Intubation should ideally be carried out by an experienced anaesthetist using general anaesthesia. This allows the epiglottis and supraglottic area of a child to be inspected under controlled conditions without the risk of precipitating total upper airway obstruction, as might happen if inspection is carried out in the conscious child with a tongue depressor. Blood cultures should be taken after intubation as these are positive in over 20% of patients, and a swab of the epiglottis should be taken while passing the tube. There may be radiographic evidence of pneumonia in about one-quarter of patients. Characteristic soft tissue changes have been described if a lateral radiographic view of the neck is obtained [59], but valuable time may be lost in obtaining the films.

Antimicrobial therapy should cover the possibility of amoxicillin-resistant  $\beta$ -lactamase-producing *H. influenzae*. The use of a third-generation cephalosporin (e.g. cefotaxime) is recommended until sensitivities are known. Amoxicillin may be substituted if the organism is not a  $\beta$ -lactamase producer, and should be continued for 2 weeks [60]. Prophylactic rifampicin for 4 days is recommended for unimmunized household contacts up to the age of 4 years. There is evidence of a decline in the incidence of paediatric supraglottitis since the introduction of *H. influenzae* type b vaccination programmes [61].

## Acute laryngitis

Laryngitis in adults may occur as part of a generalized acute upper respiratory tract infection. It may produce only a subtle alteration in the quality of the voice, obvious hoarseness or in extreme cases virtual aphonia. It is a common accompaniment of colds and sore throats. Per-

sisting hoarseness may occur because of excessive use of the voice or cigarette smoking and requires laryngoscopy to exclude a laryngeal carcinoma [62]. The use of inhaled corticosteroids is a common cause of dysphonia in respiratory practice and is dealt with in Chapter 9. Dysphonia as a result of posterior laryngitis may occur as a consequence of gastro-oesophageal reflux and these patients may respond to empirical treatment with a proton pump inhibitor such as lansoprazole [63]. It has also been described as a consequence of occupational exposure to inhaled chemicals [64]. Management of acute laryngitis is usually expectant, as the condition in adults is self-limiting. Subjective symptoms usually improve spontaneously after about 1 week in most cases so that antibiotic treatment is not warranted as a general rule. Patients are advised to rest their voice until symptoms have subsided. When attempts have been made to culture bacteria in adult cases of acute laryngitis, high isolation rates of about 50% have been reported for *Moraxella catarrhalis*, with much lower rates for *H. influenzae* and *Strep. pneumoniae* [65]. An antibiotic may be justified in patients who are professionally dependent on the quality of their voice, in which case one should be chosen that is likely to be effective against *M. catarrhalis*. Tuberculous laryngitis is now rare in Europe and North America but is seen in populations in which the prevalence of tuberculosis is high [66,67]. Other unusual causes include herpes simplex virus, varicella-zoster virus, cytomegalovirus, diphtheria, syphilis, fungal infection and actinomycosis. The clinician needs to be alert for these and other unexpected organisms in patients who are immunocompromised [68].

### Sinusitis (rhinosinusitis)

Some knowledge of sinusitis is important to the respiratory physician because it is a common cause of persistent cough and therefore referral and because of its association with lower respiratory tract infection. It is estimated to affect about 15% of the population [69]. It is defined as an inflammation of the mucous membrane lining one or more of the paranasal sinuses and is somewhat arbitrarily described as acute or chronic (see below). The nasal passages themselves may also be inflamed, hence the term 'rhinosinusitis'. The causative organisms may be viral, bacterial or fungal. Bacterial infection may be predisposed by any condition that interferes with free drainage of mucus from the sinuses, and ostial narrowing from whatever cause is of prime importance in the development of sinusitis. A common cold or allergic rhinitis results in not only hypersecretion of mucus but also mucosal oedema, which may narrow or close off the ostia through which the sinuses normally drain. Ciliary function may be impaired by inflammation and infection, with further compromise of mucous drainage, and cilia may be lost when mucosal cells undergo metaplastic change as a consequence of per-

sistent infection. Hereditary ciliary dyskinetic disorders (see Chapter 28) may also impair drainage and predispose to sinusitis as does cystic fibrosis. Infection may extend directly into the maxillary sinus as a result of dental sepsis and it has been estimated that 10% of sinus infections may arise in this way [70]. A sudden involuntary cough triggered by the act of choking on a piece of food may result in the anterograde passage of this foreign body through the nose with subsequent infection, as the author found to his cost while wolfing down the contents of a jar of pickled mussels! Immunodeficiency disorders also predispose to infection, this sometimes being caused by unusual organisms including fungi [68].

The paranasal sinuses become fully developed in adolescence, the maxillary and ethmoidal sinuses being present from birth and the frontal and sphenoidal sinuses developing in infancy. They are lined by mucus-secreting ciliated pseudostratified columnar epithelium and are normally sterile, the surface mucus being continually cleared by the concerted action of the cilia. The four pairs of paranasal sinuses (frontal, maxillary, sphenoidal and ethmoidal) communicate with the nasal cavity (Fig. 12.1) and are susceptible to the spread of infection from the nasopharynx. The maxillary, frontal and anterior ethmoidal sinuses all drain mucus by means of their 'mucociliary escalators' in much the same way as does the tracheobronchial tree. This drainage of all these three sinuses is directed through small ostia into a single narrow area known as the osteomeatal complex (Fig. 12.1a), which is situated in the middle meatus, lateral to the middle turbinate. Swelling of the mucosal lining of the middle meatus may therefore block the osteomeatal complex and interfere with the drainage of all these sinuses and it is of note that most sinus infection occurs in the spaces subtended by this complex. The posterior ethmoidal sinus drains similarly but into the superior meatus and the sphenoidal sinus more posteriorly into the sphenothmoidal recess.

### Acute sinusitis

Acute sinusitis is an infection that occurs very commonly in the population, complicating about 1 in 200 upper respiratory tract infections [29]. The initiating infection is thought to be most frequently viral, 'common cold' and other respiratory viruses having been recovered from aspirates of the maxillary sinus [72]. It is supposed that viral replication in the mucosal lining of the sinus disrupts its normal defensive mechanisms, resulting in the production of a mucous exudate that then becomes secondarily infected by bacterial pathogens with the accumulation of neutrophil-laden mucopurulent secretions within the sinuses themselves. The mucosal swelling associated with allergic rhinitis and nasal polyp formation may also produce conditions favourable to bacterial infection, as

**Fig. 12.1** (a) Coronal section through the nose and paranasal sinuses (cf. Fig. 12.2), the stippled area representing the osteomeatal complex. (b, c) Sagittal sections with (c) showing a view through the middle and superior turbinates, displaying the ethmoidal cells. (After Wald [71].)

may dental sepsis affecting the upper molars and premolars, the roots of which penetrate the maxillary sinuses.

Methods of microbiological sampling other than sinus aspiration are likely to pick up nasal commensals. The most common bacteria responsible for sinusitis in adults are *Strep. pneumoniae* and *H. influenzae* [73];  $\beta$ -lactamase production has been reported in over 15% of *H. influenzae* in some series and is increasing [74]. Although *M. catarrhalis* is a common sinus isolate in children, it is less common in adults [73]. Mixed infections are not uncommon and anaerobes may be cultured if attempts are made to do so, accounting in these circumstances for about 10% of isolates. Anaerobic infection may occur as the result of dental sepsis and is therefore more commonly found in adults. Other organisms include *Staphylococcus aureus*, *Strep. pyogenes* and Gram-negative bacteria, including *Pseudomonas aeruginosa*, which has been most commonly isolated in patients with cystic fibrosis [75]. The isolation of *Staph. aureus* may not always be significant as it is carried as a commensal in a high proportion of asymptomatic subjects but it may be a pathogen particularly in sphenoidal and frontal sinusitis [76,77].

### Chronic sinusitis

Sinusitis may be arbitrarily described as 'chronic' if it has been present for 3 months. In chronic sinusitis the ciliated columnar epithelium becomes replaced by a thickened stratified squamous lining denuded of cilia and which in advanced cases may grossly diminish the volume of the affected sinus. These changes are irreversible and result from prolonged infection, the sinus cavity continuing to harbour bacterial flora and being susceptible to repeated acute exacerbations of infection by pathogenic organisms, commonly *Strep. pneumoniae* and *H. influenzae*. Anaerobes occur more commonly in chronic than acute sinusitis.

Intractable sinusitis raises the possibility of fungal infection, which may occur in both immunocompetent and immunosuppressed patients [78]. Allergic fungal sinusitis may be suspected in atopic individuals with chronic sinus symptoms and nasal polyposis. *Aspergillus* species may be implicated as may other genera and the process may take the form of an IgE-mediated hypersensitivity reaction akin to bronchopulmonary aspergillosis [78]. Occasionally a sinus mycetoma may form within a maxillary sinus [78]. Invasive fungal sinusitis may occur acutely in immunocompromised, neutropenic, malnourished and diabetic patients, although more chronic forms that sometimes occur in immunocompetent patients are also recognized [78].

### Clinical features

The symptoms of acute sinusitis frequently follow a common cold or other viral upper respiratory tract infec-

tion but may also follow an episode of allergic rhinitis, so that any initial nasal discharge may be watery and accompanied by sneezing. All the sinuses may be affected to some extent. Maxillary sinusitis causes an uncomfortable feeling of fullness or pain over the cheek that may radiate anteriorly. There may be maxillary toothache [79–81]. Frontal sinusitis may cause supraorbital headache. Anterior ethmoidal sinusitis may give pain over the bridge of the nose and medial angle (or canthus) of the eye. Sphenoidal sinusitis may cause retro-orbital headache, which may be referred over a wide area of the scalp to the temples and occipital region. All these pains may be worsened by leaning forward or straining. Headache may be severe. There may be nasal blockage that is reflected in the quality of the voice. The sense of smell may be lost as a result of inflammation of the olfactory mucosa. With the onset of bacterial infection, there may be mucopurulent rhinorrhoea and any postnasal discharge may produce coughing. Such discharge clearly depends on the patency of the ostia. The patient may complain of an unpleasant taste and bad breath. Fever and malaise are frequent but inconstant features. The symptoms in chronic sinusitis are similar but are commonly less severe. There may be a persistent 'catarrhal' discharge.

Physical examination may show a predisposing anatomical abnormality such as a deviated septum. It may reveal reddened or oedematous nasal mucosa. Any persistent inflammation may cause the mucosa to 'balloon' with the formation of polyps, as may also happen in allergic rhinitis [82]. Purulent secretions may sometimes be present in the middle meatus of the nose and may also be seen against the posterior pharyngeal wall. The breath may smell foul, raising the possibility of anaerobic infection. There may be tenderness over an affected frontal or maxillary sinus; occasionally tenderness and swelling over the maxilla may indicate a dental abscess. Further evidence of active infection may be provided by the failure of the frontal or maxillary sinuses to transilluminate when a torch is held against them in a darkened room [83].

### Investigations

'Routine' laboratory tests such as white cell count, erythrocyte sedimentation rate and C-reactive protein are frequently normal [84]. Although paranasal sinus radiographs are a simple means of obtaining diagnostic information, they are unfortunately notoriously unreliable, even with the use of multiple projections, and cannot adequately show the anterior ethmoidal sinuses. These films may be reported as showing a variety of changes depending upon the extent of the infection, ranging from thickening of the mucosal lining, which need not indicate active disease, to an air–fluid level or complete opacification of the sinus, both of which are significant. In chronic

sinusitis the abnormalities may persist, making discrimination from an acute exacerbation difficult.

CT (Fig. 12.2) gives a much more accurate representation of pathology, the ethmoidal sinuses showing well on two axial cuts and the remaining sinuses being imaged with about seven cuts in the coronal plane, this delivering

(a)

(b)

**Fig. 12.2** Coronal CT of the paranasal sinuses for comparison with Fig. 12.1: (a) clear maxillary sinuses and ethmoidal cells with patent osteomeatal complexes; (b) a patient with chronic sinusitis showing opacification with evidence of mucosal disease in these three areas. (Films courtesy of Dr K.R. Karia.)

a comparable radiation dose to three standard radiographic views of the sinuses. One problem with CT, apart from its cost, is that although it demonstrates abnormalities with alacrity, these may not represent bacterial infection. Thus over 80% of subjects with viral 'colds' have maxillary sinus abnormalities on CT [85] and 24–39% of the asymptomatic population may demonstrate mucosal abnormalities [86]. It is probable that CT examination of the paranasal sinuses should be reserved for delineating the anatomy and pattern of inflammatory paranasal disease prior to possible surgical intervention in patients in whom medical treatment has failed or in whom an inflammatory complication or malignant disease is suspected [87]. Calcification within the sinus on CT is suggestive of fungal infection [78]. Antral puncture to enable diagnostic aspiration is seldom necessary but may sometimes be used in difficult cases or when an unusual organism is suspected, such as may be the case in an immunosuppressed patient. Endoscopically directed middle meatus aspiration culture may be an acceptable alternative [88]. Fungal sinusitis can only be reliably diagnosed by adequate aspiration with silver staining and fungal culture [78]. In the case of allergic fungal sinusitis the aspirated mucinous material, which resembles peanut butter or cottage cheese, may be the sinus equivalent of the bronchial plugging or 'mucoid impaction' associated with allergic bronchopulmonary aspergillosis. It contains hyphae but these do not invade the submucosa and adjacent tissues. The use of ultrasound, in experienced hands, is about as reliable as radiography in diagnosing fluid retention in the maxillary sinuses [89].

### Treatment

Time-honoured measures to obtain symptomatic relief in acute sinusitis include the inhalation of moist warm air, compliance being encouraged by the addition of a volatile aromatic substance such as benzoin tincture compound BP (Friar's balsam). The use of topical decongestant drops, such as ephedrine 0.5%, may also produce relief. This and other sympathomimetic agents may give rise to rebound vasodilatation and congestion as their effect wears off and their prolonged use is not encouraged. They may be more effective if applied in the head-down position and this attitude held for 2 or 3 min. Simple analgesia may be necessary. Predisposing allergic rhinitis should be treated with antihistamines and topical steroids or sodium cromoglycate (cromoglycate).

There is a dearth of well-constructed, placebo-controlled, double-blind, randomized trials of antibiotic treatment in adult patients presenting with symptoms suggestive of acute sinusitis in primary care; the few that have been carried out do not show consistent superiority of response in the antibiotic-treated groups [90–92]. Whereas patients who have only mild symptoms may be

managed expectantly, it is nevertheless usual to treat those with more severe or persistent symptoms with an antibiotic. Effective management of such cases of acute or acute-on-chronic sinusitis usually depends on the selection of an antibiotic appropriate to the infecting organisms. As reliable identification of the pathogen in an individual patient is impossible without direct needle puncture of the involved sinus, treatment is empirical and designed to deal with the likely pathogens. A reasonable initial choice for the community-acquired case in most of the UK is amoxicillin 500 mg 8-hourly or, in penicillin-allergic patients, trimethoprim 200 mg 12-hourly. Both of these inexpensive preparations have a spectrum of activity that can still deal with *Strep. pneumoniae* and *H. influenzae* more often than not. In cases where infection is more severe or if it remains unresponsive after 7–10 days of treatment, the spectrum may be broadened to cover  $\beta$ -lactamase-producing *H. influenzae* and *M. catarrhalis* by substituting amoxicillin-clavulanate (co-amoxiclav) or, in the penicillin-allergic patient, one of the newer macrolides such as clarithromycin is an option. There are many alternatives and a knowledge of local patterns of antimicrobial resistance is helpful in making a rational choice; thus in geographical locations where there is a high prevalence of  $\beta$ -lactamase-producing aminopenicillin-resistant *H. influenzae*, these can be covered from the outset. There is little information about the optimal duration of antimicrobial treatment but it is logical in acute sinusitis to extend the course to 14 days because of the walled-off nature of the infected spaces. Antimicrobial treatment in chronic sinusitis may be prolonged for 1 month or more, the optimal length of treatment remaining *sub judice* [93]. Where the sinus infection is thought to be associated with dental sepsis, co-amoxiclav in combination with metronidazole are reasonable options, although the sinus infection will recur until the predisposing dental cause has been satisfactorily dealt with.

In the unusual and difficult case, the sinus contents may be aspirated by direct puncture and submitted for culture, the appropriate antibiotic being selected on the basis of sensitivities. This may be necessary where it is thought that the infection has been acquired in hospital or where unusual organisms are suspected in immunocompromised patients. In these situations it is advisable to institute urgent treatment with broad-spectrum parenteral antibiotics to cover not only the usual bacterial pathogens but also *Ps. aeruginosa*, Gram-negative enteric bacilli and anaerobes while awaiting the outcome of investigations [68]. Invasive fungal sinusitis may occur acutely in neutropenic, malnourished and diabetic patients [78]. It is confirmed by isolation of the organism from sinus contents and by demonstrating mucosal and bony invasion on surgical biopsy material, treatment being by adequate surgical clearance of infected material and administration of amphotericin. More chronic invasive forms are also

described, usually but not invariably in patients with impaired immunity, and these too require surgical and antifungal treatment [78]. Allergic fungal sinusitis is treated surgically with removal of polyps and inflammatory material. The condition tends to recur and surgical follow-up is necessary [78]. It is not yet clear whether systemic steroids prevent recurrence but they may be used in the short term after surgical clearance, and are followed by long-term intranasal steroids [94].

### Surgery

Surgical treatment may become necessary when:

- 1 sinusitis becomes chronic, with poor control of symptoms despite seemingly appropriate medical treatment;
- 2 a predisposing anatomical abnormality needs correction in order to achieve adequate drainage;
- 3 complications either occur or are considered likely to happen [95].

Whereas earlier surgical attempts concentrated on the maxillary sinuses, with inferior meatal antrostomy and the more radical Caldwell–Luc procedure of sublabial antrostomy, more recent technological advances have provided ear, nose and throat surgeons with an accurate CT ‘road map’ of their territory and the endoscopic means to modify it, particularly in the crucial region known as the osteomeatal complex (see Fig. 12.1a), the small space into which the maxillary, frontal and anterior ethmoidal sinuses all drain. This has led to the development of functional endoscopic sinus surgery, the aim of which is to eradicate ethmoidal disease with the resolution of severe mucosal changes and the re-establishment of proper sinus ventilation and drainage [96,97]. This usually involves dissection of the ethmoidal sinuses and removal of the uncinate process and diseased mucosa. It is followed by a prolonged period of regular nasal douching and antibiotic treatment until infection is eradicated and mucosal changes have reversed. The complication rate in experienced hands is low but problems include blindness as a result of damage to the optic nerve, intraorbital haemorrhage and infection, damage to the internal carotid artery and leakage of cerebrospinal fluid through a damaged cribriform plate.

### Complications

The complications of sinusitis are due to the spread of infection to the contiguous cranial cavity and orbit [98–101]. These problems are unusual in economically developed societies given the ready availability of antibiotics. Intraorbital cellulitis or abscess formation may cause proptosis and threaten vision, so that urgent axial CT, antibiotics and surgical drainage of significant accumulations of pus are called for. Spread of infection from the eth-

moidal and sphenoidal sinuses may result in cavernous sinus thrombosis, while spread from the frontal sinuses may cause intracranial sepsis. Osteomyelitis with destruction of the bony margins of a sinus may also occur; ‘Pott’s puffy tumour’, described in the pre-antibiotic era, is caused by osteomyelitis of the frontal bone.

## Acute bronchitis, tracheitis and tracheobronchitis

All three terms refer to common inflammatory conditions affecting a part or the whole of the tracheobronchial tree. These conditions, which overlap and are ill-defined clinically, frequently follow infection with any of the common cold viruses. Acute bronchitis is common during epidemics of influenza and measles may also be causally related. *Mycoplasma pneumoniae* or *Bordetella pertussis* may also occasionally initiate infection. Secondary bacterial infection may follow an initial viral insult, *H. influenzae* and *Strep. pneumoniae* being common isolates; *Staph. aureus* is less common but may complicate influenza. Seasonal variations occur, acute bronchitis being reported more commonly in the winter months [102]. Varying degrees of inflammatory change are found in the respiratory mucosa, depending on the responsible organisms, and tend to be more severe in influenza than in rhinovirus infections [103,104].

### Clinical features

Tracheobronchitis may affect any age group but has been reported more commonly in children and the elderly [102]. An affected adult commonly complains that ‘the cold has gone on to my chest’, which usually means that acute coryza or symptoms of pharyngitis have been followed by a cough which persists once the original symptoms have abated. The cough is often dry at first but later frequently becomes productive of mucoid or mucopurulent sputum. This sometimes contains streaks of blood for short periods, a symptom that may alarm otherwise stoical patients sufficiently to cause them to seek medical advice. A fever with symptoms of rhinovirus infection is less common in adults than in children but is common when the infecting organism is an influenza virus, *Mycoplasma pneumoniae* or an adenovirus.

Patients affected by acute bronchitis are often previously healthy; however, in a tobacco smoker who already has a chronic productive cough, albeit mild, the infective episode may be termed ‘acute-on-chronic bronchitis’ or ‘acute exacerbation of chronic bronchitis’ or ‘acute exacerbation of chronic obstructive pulmonary disease’. Otherwise healthy smokers who develop acute bronchitis tend to cough for longer than similarly afflicted non-smokers [42]. Breathlessness and cyanosis do not occur unless the patient has coexisting cardiopulmonary disease or unless

the acute bronchitis is complicated by pneumonia. Wheezing is not usually a feature in adults, unless the patient has chronic bronchitis or asthma, but is more common in children, many of whom do have asthma. When tracheitis is present the patient may complain of, or admit to, retrosternal discomfort or tightness, sometimes described as burning, that may be heightened by inspiration or coughing.

Physical examination of the chest commonly reveals no sign of disease. Low-pitched wheeze and coarse crackles may be heard, and if this is the case they may frequently be shifted if the patient coughs, thereby clearing the larger airways of loose secretions. Higher-pitched wheeze is unusual and is suggestive of asthma or chronic obstructive pulmonary disease.

### Diagnosis

The diagnosis is based on the history and the self-limiting nature of the illness. Attention should be paid to detail, and if the cough lasts longer than 2 weeks a chest radiograph should be obtained, this being normal in uncomplicated acute bronchitis. Persistent symptoms in a tobacco smoker may be an indication that more serious respiratory disease has perhaps become superimposed on underlying simple chronic bronchitis, the patient or spouse frequently noticing a change in the character of the cough or some other new feature that should alert the physician to investigate further for neoplastic disease. Haemoptysis in a cigarette smoker over the age of 40 years usually merits a bronchoscopy despite a normal chest film [105]. Attempts to identify a viral cause in acute tracheobronchitis do not result in information of any practical use and, although of possible epidemiological interest, are omitted in ordinary clinical practice. However, mucopurulent sputum may be cultured for bacterial pathogens.

### Treatment

Treatment of acute tracheitis or tracheobronchitis in previously healthy subjects is usually confined to the provision of symptomatic remedies. If cough proves tiresome it may be relieved by codeine linctus. Expectorant preparations have no value [106]. When the patient is febrile, rest and attention to hydration should be encouraged. If the sputum is mucopurulent, an antibiotic such as amoxicillin 250 mg 8-hourly or clarithromycin 250 mg 12-hourly may be prescribed, 7 days of treatment usually being sufficient provided that the organism is sensitive. Antibiotic treatment is more important in patients with coexisting cardiopulmonary disease but may sometimes be omitted in otherwise healthy people with mild infections [107].

## Other forms of tracheobronchitis

### *Fungal tracheobronchitis*

Fungal tracheobronchitis may occur in immunocompromised patients. *Aspergillus* species may be responsible and cause a rapidly evolving, often fatal, febrile respiratory distress syndrome with necrosis, ulceration and the formation of pseudomembranes that may obstruct the tracheobronchial tree [108–110]. Treatment of serious fungal tracheobronchitis in immunocompromised patients is with amphotericin.

### *Diphtheria*

Diphtheria may spread from the pharynx to involve the larynx and tracheobronchial tree, sometimes leading to asphyxia as a result of membrane formation in the respiratory tract [111]. There may be a greyish-white tonsillar membrane. Morbidity and mortality relate not only to the effects of airway obstruction but also to the production of endotoxin, which may result in myocarditis and peripheral neuropathy, so that diphtheria is treated with both diphtheria antitoxin and penicillin or erythromycin. The condition occurs in unimmunized populations and there have been recent epidemics in Russia [111].

### *Acute laryngotracheobronchitis*

Acute laryngotracheobronchitis in children produces the syndrome known as 'croup', which is of interest to adult respiratory physicians chiefly when it affects their own issue. The peak age of onset of croup is 1–2 years, when the diameter of the trachea is relatively small. Croup is characterized by a barking cough, a hoarse voice and inspiratory stridor with distressed breathing. It is commonly preceded by a cold and is usually the result of parainfluenza virus infection, although other viruses may also be causal, including RSV, rhinoviruses and adenoviruses [112]. Treatment is supportive and the steam kettle traditional. The development of sternal and intercostal recession with a rising pulse and respiratory rate are indications for hospital admission, which occurs in about 10% of cases, in order to provide a higher level of supportive care. Nebulized budesonide may help to diminish local inflammation and oedema.

Croup needs to be distinguished from bacterial tracheitis, sometimes called bacterial or pseudomembranous croup, a toxic condition with a high pyrexia that may occur throughout childhood. *Staph. aureus* is most frequently implicated but other pathogens, including *H. influenzae*, *M. catarrhalis*, group A haemolytic streptococci and *Strep. pneumoniae*, have been isolated. It is suspected that this condition represents bacterial superinfection fol-

lowing an initial viral insult. The trachea may become obstructed by purulent secretions so that ventilatory support may become necessary [112].

## Influenza

Influenza is an acute, usually self-limiting, febrile illness of viral origin that differs from other respiratory viral infections with respect to both the mortality it may cause and the epidemic outbreaks for which it has become infamous.

### The virus

The influenza virus is assigned to the Orthomyxoviridae family. There are two generic types, A and B, type C belonging to another genus. Within these types, both subtypes and strains are described, depending upon the antigenic structure of the individual virus particles. Type specificity is based upon the antigenicity of their ribonucleoprotein (nucleocapsid) composition. Subtypes and strains are characterized by antigenic changes in the haemagglutinin (H) and neuraminidase (N) glycoprotein 'spikes' that constitute a major part of the virus envelope [113]. For any influenza virus the letter A, B or C therefore refers to the *type*; the *subtype* is denoted by the haemagglutinin (H<sub>1</sub>, H<sub>2</sub> or H<sub>3</sub>) and neuraminidase (N<sub>1</sub> or N<sub>2</sub>) present; and the *strain* is denoted by the place and the year in which the virus was first isolated. Thus A/Scotland/74/H<sub>3</sub>N<sub>2</sub> refers to a type A influenza virus of subtype H<sub>3</sub>N<sub>2</sub> isolated in Scotland in 1974.

Outbreaks of influenza occur within communities every 1–3 years, often first declaring themselves by an increased number of febrile respiratory illnesses in young school-children, who are the most susceptible group, and thereafter in the adult population. Reporting systems vary according to national practice. In England and Wales an epidemic is declared by the Communicable Disease Surveillance Centre based at Colindale when the weekly incidence of reported influenza cases exceeds 100 per 100 000 people in the population in question. This monitoring is dependent on numbers of 'influenza-like illnesses' reported by spotter practices as well as serological reports from public health virology laboratories.

Outbreaks tend to be abrupt, the peak of an epidemic occurring within 1 month in an affected community and the numbers of new cases tailing off over the following few weeks [114]. Average attack rates are about 20% of the population but may be as high as 50% in certain sections of the community [115]. Epidemics in the Northern Hemisphere occur in the colder months from October to May. Sporadic cases may occur in the summer months but are rare. At variable and unpredictable intervals, usually 10 years or more, waves of infection have spread across

the world, reaching pandemic proportions. The largest recorded pandemic occurred between 1918 and 1919 when so-called 'Spanish flu' resulted in 20 million deaths worldwide in one winter, over 0.5 million of them in the USA and an estimated 200 000 in England and Wales [116,117]. This was therefore the worst infectious pandemic in history, accounting for many more deaths than the hostilities of the first World War. Subsequent pandemics occurred in 1957, 1968 and the most recent in 1977. In the USA, influenza is estimated to kill 10 000 people annually in non-epidemic years and at least 30 000 people during epidemics [118] so that it is rightly regarded as a major public health problem.

### Antigenic drift and shift

Spontaneous changes in the antigenicity of influenza A virus particles are particularly characteristic of this disease and are considered to be responsible for its epidemic behaviour. These antigenic variations result from spontaneous mutations affecting the RNA coding of the surface N and, more frequently, H glycoproteins. When these antigenic changes are minor mutations in response to host immunological pressure, they are referred to as *drift* and may result in epidemics. When a major antigenic variation in N or H glycoprotein occurs, the change is referred to as *shift* and pre-existing immunity to 'old strains' confers little or no protection against the new mutant virus, which is likely to sweep through the population in pandemic fashion. Subsequent epidemics involving the same subtype with minor antigenic variations (drift) occur every few years, during which time the population's level of immunity increases until such time as a further major shift occurs, with pandemic consequences. Such shifts occurred in the severe pandemics of 'Asian flu' in 1957 (A/H<sub>2</sub>N<sub>2</sub>), the moderate pandemic of 'Hong Kong flu' in 1968 (A/H<sub>3</sub>N<sub>2</sub>) and the mild pandemic of 'Russian flu' in 1977 (A/H<sub>1</sub>N<sub>1</sub>), all of which are thought to have originated in China. The severe 1918 outbreak is thought to have been A/H<sub>1</sub>N<sub>1</sub> [119], bearing some antigenic resemblance to the 1977 virus. The fact that the A/H<sub>1</sub>N<sub>1</sub> era continued until 1957 may account for the mild nature of the 1977 pandemic, much of the world population still having some immunity to the earlier virus.

Such major antigenic shifts may reflect recombinational events, i.e. genetic intermingling between animal and human virus genes that allows spread and pathogenicity amongst humans. It has been speculated that the introduction of such new strains may come from aquatic bird reservoirs emerging in southern China, with pigs as intermediates or 'mixing vessels' as they possess receptors for both avian and human influenza viruses [120]. South-East Asian rural domestic practices, where humans live under the same roof as fowl and pigs, may facilitate these

processes. In such circumstances, the prevailing human H or N gene may be replaced by the allelic gene of an animal influenza virus via reassortment. There was recent international anxiety because of a small outbreak of 'Chinese avian influenza' in Hong Kong, in which a previously recognized avian strain (A/H<sub>5</sub>N<sub>1</sub>) believed to cause disease only in birds caused a number of human cases, with some deaths. This fuelled speculation about the possible beginning of a new pandemic caused by a major antigenic shift, although fortunately there has been no evidence so far of person-to-person spread. The entire chicken population of Hong Kong was nevertheless slaughtered as a precaution [121].

There is no clear explanation why epidemics occur only in winter months [122]. Influenza B produces lesser epidemics and lower mortality than influenza A, and influenza C is not thought to cause epidemics at all, occurring only sporadically. The influenza virus is transmitted from person to person in respiratory secretions, most probably in the form of a small-particle aerosol produced when an infected person coughs, sneezes and talks [123]. The incubation period is 18–72 h, the virus entering and replicating in respiratory epithelial cells unless the exposed subject is protected by specific IgA antibody. Once replication has occurred, the host cell dies and nasal and tracheobronchial epithelial cells desquamate; these are shed with the release of more virus particles, which in turn infect adjacent cells. The virus continues to be shed in respiratory secretions for about 1 week, rising to a peak at about 48 h, high numbers of viral particles being shed by symptomatic patients [124].

### Clinical features

The subject with partial immunity to an infecting strain of influenza may shed and transmit the virus without developing more than the mildest of symptoms [125]. However, those with little or no immunity develop an abrupt and often prostrating febrile illness, non-specific symptoms including malaise, feelings of hot and cold, anorexia, myalgia, a sore throat, an initially dry cough and headache. The degree of prostration is usually commensurate with the level of the fever which, in the absence of antipyretic therapy, runs in continuous fashion between 38 and 40°C over the course of 3 or 4 days. Once the fever has settled recovery is usually rapid and accompanying symptoms generally clear within a week or two, although the cough may persist for longer. Physical signs are non-specific, the patient appearing flushed and unwell. A few small cervical lymph nodes may be palpable as with any pharyngitis. The chest is usually clear to auscultation in uncomplicated cases. It should be appreciated that the symptoms and signs are often indistinguishable from those produced by other respiratory viruses that may be active in the community at the same time.

### Complications

The effects of the influenza virus may occasionally extend beyond the nasopharynx, with resultant laryngotracheobronchitis and/or pneumonia. Influenza, in common with other respiratory virus infections, may result in exacerbations of chronic obstructive pulmonary disease [126,127]. Laryngotracheobronchitis may also occur, and in the first 5 years of life mucosal oedema may give rise to sufficient upper airway narrowing to cause the barking cough and inspiratory stridor that typify croup. Sinusitis and middle ear infections may also occur. The hospital mortality from the respiratory complications of proven influenza may be high, 39% of 36 cases of influenza admitted to Nottingham hospitals dying as a consequence of their illness [128].

### Pneumonia

A prospective British Thoracic Society survey that included 453 patients with community-acquired pneumonia found evidence of influenza A virus infection in about 7% of cases [129]. Pneumonia usually develops as a result of secondary bacterial infection, although primary influenzal pneumonia can occur [130,131]. If respiratory symptoms are severe in a suspected case of influenza or if they do not show the expected improvement within 1 week, a chest radiograph should be obtained and any sputum cultured in order that bacterial infection should not be overlooked.

#### *Primary influenza virus pneumonia*

Primary influenza virus pneumonia (see Chapter 13) is a diagnosis of exclusion made when the usual clinical features of influenza are accompanied by breathlessness and hypoxia, with bilateral non-homogeneous shadowing on the chest radiograph, the absence of a bacterial pathogen in the sputum and subsequent confirmatory serological testing. This complication can occur in a previously healthy subject and carries a high mortality. Although unusual it may be encountered during epidemics. Those cases coming to postmortem examination show inflammation and necrosis of the laryngotracheobronchial mucosa and a haemorrhagic pneumonia with relatively few intra-alveolar inflammatory cells.

#### *Secondary bacterial pneumonia*

Secondary bacterial pneumonia (see Chapter 13) may complicate influenza, particularly in the elderly or those with chronic cardiopulmonary disease. This complication may occur at an early stage of infection or after the patient has shown initial signs of improvement. The most frequent pathogen is *Strep. pneumoniae* followed by *Staph.*

*aureus*, which is more feared, and *H. influenzae* [132]. These infections are characterized by signs of consolidation, are often unilateral with lobar or segmental distribution and are usually responsive to appropriate antibiotic treatment. It is strongly recommended that antimicrobial therapy in patients who develop pneumonia during influenza epidemics should include cover for *Staph. aureus*. The fungus *Aspergillus fumigatus* may occasionally cause severe pneumonia after influenza.

### Non-respiratory complications

Central nervous system complications include encephalitis, transverse myelitis and Guillain-Barré syndrome, although definite aetiological links between these conditions and influenza virus infection remain somewhat tenuous [133–136]. All these complications are rare and have been described either at the height of the illness or during the recovery phase. Encephalitis is attended by drowsiness and confusion, sometimes leading to seizures and coma, in which case the prognosis is poor. Transverse myelitis may produce girdle pain at the level of spinal cord involvement, this being followed by a sensory and motor deficit with a clear sensory level detectable on physical examination. Loss of bladder control and paraparesis are usual accompaniments. Although recovery is frequent the outcome is somewhat unpredictable. Guillain-Barré syndrome (infective polyneuropathy) may cause peripheral sensory loss and limb weakness, sometimes starting in the legs and progressing upwards to cause a flaccid paralysis with absent tendon reflexes. Respiratory muscle paralysis and bulbar palsy may occur. The cerebrospinal fluid characteristically shows a high protein content with a normal or minimally raised white cell count. In encephalitis and transverse myelitis, the protein and cell counts are variable depending upon the degree of inflammatory response present. Reye's syndrome may occur as a complication of a wide range of viral infections, not all of them respiratory, but is particularly associated with epidemic influenza B and, to a lesser extent, influenza A infection [137]. It is almost entirely confined to children aged between 2 and 16 years and results in both cerebral and hepatic dysfunction, the former leading to coma and the latter to measurable disturbances of liver function. The pathophysiology is incompletely understood, although the observed increase in frequency of Reye's syndrome in children who have received aspirin for influenza [138] has led to the recommendation that salicylates are contraindicated in children with febrile illnesses. The mortality of Reye's syndrome approaches 40%. Other rare complications include myositis [139], with muscle pain and weakness associated with a high creatine kinase level sometimes with myoglobinaemia and renal failure, and myocarditis/pericarditis [133] that may be accompanied by cardiac dysrhythmias. A causal association between

influenza A infection and fetal loss has been suspected but not substantiated [140].

### Diagnosis

The diagnosis is often accurately made on clinical grounds when data from the Public Health Laboratory Service or the Centers for Disease Control indicate that an epidemic is occurring in a particular region. Serological evidence (usually by complement fixation or haemagglutination inhibition tests), although of epidemiological interest, is of limited clinical value because of the requirement for a convalescent sample, a fourfold change in titre being confirmatory [141]. The influenza virus can be directly identified in nasal or throat secretions or from sputum within a few hours by immunofluorescent antibody techniques, ELISA or gene amplification where facilities are available. Immunofluorescence has the advantage of being relatively cheap but sensitivity is poor compared with cell culture methods [117], which may be used if it is necessary to accurately type the virus.

### Treatment and prevention

In the majority of cases the treatment of influenza need be supportive only, the patient being advised to rest and to take liberal oral fluids. Paracetamol or aspirin may be used as antipyretic agents, although the latter should be avoided in children because of the risk of Reye's syndrome. A broad-spectrum antibiotic is indicated in patients who develop evidence of secondary bacterial infection; when severe community-acquired pneumonia is present, antimicrobial cover should include drugs active against *Staph. aureus*. There are a number of agents that have been shown either to have significant antiviral effects when used as treatment once infection has developed or to be prophylactic during outbreaks. These agents are described in Chapter 9 but are mentioned below.

### Antiviral drugs

Amantadine and rimantadine (see Chapter 9) are adamantanes that are broadly similar both structurally and in their mechanisms of action. They are about as effective as available vaccines in preventing influenza A virus infections, and when used as treatment shorten the duration of the illness [125,142]. They may be used prophylactically in susceptible individuals such as the elderly and in those with coexisting cardiopulmonary disease, being potentially useful in situations where vaccination has not been given and where infection seems likely, as might be the case for those living in crowded conditions during an epidemic [143]. Amantadine need only be taken for 2 weeks in these circumstances, provided that vaccination is given simultaneously. It may also

be taken throughout an epidemic in the following circumstances:

- 1 by patients in whom vaccination is contraindicated because of hypersensitivity to hens' egg products;
- 2 if the vaccine becomes unavailable;
- 3 by healthcare workers in major epidemics in order to reduce disruption in the delivery of their service.

Amantadine is prescribed at a dose of 100mg daily in patients aged over 65 years (see Chapter 9). Central nervous system side-effects such as headache, dizziness and sleep disturbance may occur but are usually mild.

Adamantanes may also be used as treatment in patients in whom a clinical diagnosis of influenza has been made, particularly in those in whom complications might be expected to occur, such as the elderly or those with chronic cardiac or respiratory disease. It is reasonable to treat as soon as possible after the onset of symptoms and to continue for up to 1 week in such circumstances. It is unwise to use these drugs for both postexposure prophylaxis and treatment in the same home because the selection and transmission of resistant influenza A virus may occur.

Rimantadine (see Chapter 9) is an alternative and structurally related adamantane that is available in the USA but not in the UK. It reportedly has fewer central nervous system side-effects [144]. Zanamivir (see Chapter 9) is a sialic acid analogue that selectively inhibits both influenza A and B neuraminidases (sialidases). Clinical trials suggest that in otherwise healthy patients with influenza A or B infection it may reduce the median duration of symptoms by 1–2 days if a 5-day course of inhaled treatment is initiated within 48 h of the onset [145]. There are, as yet, no comparative studies of adamantanes and zanamivir.

### Vaccination

Influenza vaccination is the most satisfactory prophylactic measure and is justified by a mortality rate of 1–2 per 10 000 cases of influenza per year [146]. In the USA the total excess deaths has been estimated to be 10 000–40 000 per year, being particularly high in the elderly and those with serious coexisting disease [118]. In the UK the annual number of deaths attributed to influenza is 3000–4000 in most years, although these figures rise substantially in epidemic years such as the winter of 1989–90 when it is estimated that 30 000 deaths may have been caused [147].

The available vaccines contain formalin-inactivated influenza virus that has been cultured in embryonated hens' eggs and which *cannot* cause influenza. The viral components contained in the vaccine are reviewed annually and modified according to World Health Organization recommendations based on the A and B virus subtypes most prevalent in the preceding winter. Current activity still relates to strains of influenza A subtypes H<sub>1</sub>N<sub>1</sub> and H<sub>3</sub>N<sub>2</sub> with sporadic cases of influenza B strains, so that these constituents are incorporated in trivalent vaccines. Modern vaccines may be effective in preventing

illness in 60–70% of recipients, and in those subjects who contract influenza despite vaccination its severity and complication rate is reduced [148]. In patients over the age of 60 years the risk of influenza infection has been shown to be halved [149]. The vaccine takes 1–2 weeks to achieve protective antibody levels and must be repeated annually, protection lasting for only one season [150].

Vaccination is recommended for elderly people, especially those who live in institutions such as nursing and residential homes, and for patients with chronic cardiac or pulmonary disease (including asthma), chronic renal failure, diabetes mellitus and those whose immunity is otherwise compromised as a result of disease or its treatment [151–153]. The rationale for these recommendations is based on observations that influenza-associated mortality increases substantially in the seventh and eighth decades [154,155] and in the presence of serious coexisting medical complaints [155,156]. The aim of the annual vaccination programme in the UK is to encourage the vaccination of 'high-risk' patients by early November each year. The target population in England and Wales is estimated to be about 6 million people or 11.8% of the population as a whole [157]. Uptake in this group has been found to be less than 50%. The spread of influenza in hospitals and nursing homes may also be reduced if medical and nursing staff are vaccinated. This is not currently recommended as a routine measure in non-pandemic years in the UK, although it is in the USA [151].

Employers sometimes consider offering influenza vaccination to their employees with a view to reducing sickness absence rather than from more altruistic motives. Such action may not be justifiable on economic grounds since the number of cases prevented are likely to be small because (i) uptake of offered vaccination is often low, (ii) large epidemics are relatively infrequent and impossible to predict accurately, and (iii) the attack rate even in epidemics is only about 20% [158]. There is also a high prevalence of other non-influenzal respiratory illness at the same time of year that is also likely to result in absences from work.

Influenza vaccination may cause local reactions in up to 50% of recipients and 2% may experience low-grade febrile reactions in the first 24 h, although these are more common in young subjects than the elderly, in whom they occur with similar frequency in groups treated with placebo [159]. The mass influenza vaccination programme carried out in the USA in 1976 against swine influenza was associated with one case of Guillian–Barré syndrome per 100 000 cases inoculated and with one consequential death per 2 million recipients [160]. Such a fatality has not knowingly been associated with vaccines in later years. The vaccine is given by deep subcutaneous or intramuscular injection and should not be administered to subjects with a history of hypersensitivity to hens' eggs.

A live attenuated trivalent vaccine administered by nasal spray has recently been the subject of a clinical trial

in children in the USA [161], this type of vaccine having been previously used in the former Soviet Union. It contained the same influenza A and B virus strains used in that year's standard inactivated influenza vaccine and was found to be effective. Such a vaccine may prove useful for certain groups of children, such as those at high risk of developing otitis media, and also high-risk adults [162].

### **Pertussis (whooping cough)**

Pertussis or whooping cough is a clinical syndrome caused by the genus *Bordetella*, of which *B. pertussis* is the most common species. Infection with this minute coccobacillus results in the elaboration of local toxins that cause ciliostasis with inflammation and oedema of the tracheal and bronchial mucosa, which may lead to necrosis with sloughing of cells. Despite a worldwide vaccination programme, pertussis remains a serious global problem, particularly in developing countries. It has been estimated that 40 million cases of pertussis occurred worldwide in 1994 [163]. The illness is endemic in the UK and the USA, being highly infectious and occurring either in epidemic form in susceptible groups or sporadically in unimmunized populations [164]. It is spread by droplet infection and has a peak incidence in the later winter months and early spring. Public anxiety regarding possible neurological sequelae of vaccination led to epidemics in the UK in the late 1970s and 1980s [165], although uptake of vaccination is once again high in the UK. Whooping cough is highly communicable, affecting 70% of unvaccinated family contacts and 20% of those who have been vaccinated [166,167]. It produces only mild illness in infected adults and adolescents but these groups may be the source of potentially life-threatening illness in infants.

### **Clinical features**

The incubation period is 7–10 days, after which the patient, usually a young child, develops prodromal symptoms with a low-grade fever, malaise, profuse rhinorrhoea, sneezing and sometimes conjunctivitis. This so-called catarrhal stage lasts about 1 week and is indistinguishable from a variety of viral upper respiratory tract infections. A dry cough develops during the first few days of the illness. This progresses to distressing short bursts of paroxysmal coughing without an inspiratory pause between coughs, so that the patient may become almost apnoeic, cyanosed and often vomits. Each paroxysm may culminate in a long inspiratory effort through the partly closed glottis, a manoeuvre that produces the inspiratory stridulous 'whoop' from which this illness derives its name. The patient is most infective in the catarrhal stage, communicability falling off in the paroxysmal stage. Although the cough frequently starts to improve within 4 weeks of the onset of the illness, the paroxysmal stage may last 6–8 weeks and the cough may take several months to

clear completely. Whooping is unusual during this convalescent stage but it can recur as a result of other coincidental upper respiratory tract infection. The presence of a whoop is not a prerequisite for the diagnosis and may indeed be absent in many cases.

Whooping cough is most dangerous when it affects an infant in the first year of life, about three-quarters of all pertussis-associated deaths occurring in this age group [168]. In older children it causes an unpleasant illness but is rarely fatal in those aged over 5 years. Adolescents and adults may be infected, in which case the cough need not be paroxysmal or associated with a whoop and may be of shorter duration. Nevertheless these individuals serve to transmit infection in the community [169] and may experience an unpleasant cough for a prolonged period. The diagnosis of pertussis should therefore be a consideration in adults and teenagers with persistent cough. Persistent sore throat may be another feature [170].

### **Diagnosis**

The diagnosis is often based on the clinical history of a paroxysmal cough lasting for 2 weeks during a community outbreak [171,172]. There are various laboratory methods for detecting *B. pertussis*, its products or the patient's immunological response [173]. Microbiological confirmation is usually obtained using per-nasal calcium alginate (rather than cotton) swabs, which are positioned in the nasopharynx to induce a cough and then immediately plated on to Bordet–Gengou medium. Positive cultures may be obtained in only about 30% of cases [166], although these rates may be increased by repeated swabbing. Respiratory secretions may also be examined directly using a fluorescent antibody technique, thereby avoiding the 4-day wait inherent in the culture method, the organism being relatively slow-growing. However, false-negative results are still common. Unfortunately this and other newer techniques are not widely available and traditional culture methods do not lend themselves to use in general practice [174], although positive results from per-nasal nasopharyngeal swabs may be obtained up to 3 months from the onset of the illness when coughing persists [175]. It should be noted that positive cultures may sometimes be obtained from asymptomatic individuals. A raised white cell count (predominant lymphocytosis) is a common finding. The chest radiograph may show evidence of peribronchial thickening that overlies the cardiac contours and this need not indicate pneumonic change [176].

### **Treatment**

Children in their first year are at the highest risk and the disease at its most severe in the first 3 months of life, so that it is usual for infants below the age of 6 months to be admitted to a paediatric unit where appropriate

supportive care can be provided. Other categories of patient may be satisfactorily managed at home. Erythromycin has been shown to be active *in vitro* against *B. pertussis* [177]; although also active *in vivo* in the eradication of nasopharyngeal infection, it was initially not thought to alter the course of the illness once it had become well established [178]. More recent data have indicated that erythromycin does appear to reduce both the severity and duration of the disease even if started in the paroxysmal stage, so that it has become accepted practice to prescribe this drug for 14 days to infected cases [179]. Although the 2-week course was thought to be optimal in terms of eradicating infection with *B. pertussis*, this recommendation has not been based on prospective controlled studies and a recent trial showed no significant difference in failure rate (bacteriological persistence or relapse) between two groups treated with 7 and 14 days of erythromycin estolate respectively [180]. It is probable that a 7-day course of clarithromycin or a 5-day course of azithromycin is as effective [181].

There was similar doubt about whether erythromycin would be effective prophylaxis for family contacts, thereby helping to contain household transmission and wider outbreaks [182,183]. However, a more recent retrospective cohort study of 246 families has shown that the secondary attack rate was reduced from 25% in families without erythromycin prophylaxis to 17% in families in whom prophylaxis was used. When prophylaxis was used before the onset of a secondary case, it was found that the secondary attack rate was 4% compared with 35% when it was given after a secondary case [184]. It is current practice for antibiotic prophylaxis to be recommended for contacts of active cases and it is now generally accepted that this is an important factor in controlling outbreaks [185].

## Complications

The most common early complications are otitis media and pneumonia, both of which are caused by secondary bacterial infection that is treated with appropriate antibiotics. Occasionally the retention of sticky secretions may cause segmental or lobar collapse. Infants may convulse, though whether this is due to hypoxaemia or to some other cause is unknown. Paroxysmal coughing may cause epistaxes and conjunctival or petechial haemorrhages on

the face. Pneumomediastinum or rarely pneumothorax may occur. Before the availability of antibiotics, whooping cough was a major cause of mortality in children and still is in poor countries, death usually resulting from pneumonia due to secondary infection with other bacteria. Bronchiectasis was a serious long-term complication [186]; although this is now seldom the case in Europe and North America, nevertheless subjects with a past history of pertussis infection do have more respiratory symptoms than controls and may show minor impairments of measured lung function [187].

## Prophylaxis

The most effective form of prophylaxis is active immunization with pertussis vaccine. This is usually administered as a primary course of 'triple vaccine' (diphtheria, pertussis and tetanus), the first inoculation being given at 2 months and the second and third at 3 and 4 months [153]. Detailed guidance on immunization has been published by the Joint Committee on Vaccination and Immunization and the British National Formulary [153,188]. Convulsions and encephalopathy were considered to be rare complications but such reports may have been coincidental, no epidemiological link having been conclusively shown. Such problems, although of obvious concern, pose a much smaller risk to the population than the known mortality and complications arising from the development of pertussis infection in unvaccinated infants; indeed neurological complications after whooping cough itself are much more common than following the vaccine. However, immunization should not proceed when an earlier dose has caused a severe general reaction [153]. Where there has been a severe local reaction or pyrexia, acellular pertussis vaccine, which has a lower reactogenicity, may be substituted for later doses [153]. It is believed that neither pertussis immunization nor pertussis infection in childhood provide lifelong immunity from reinfection [189]. Since recent epidemiological studies have indicated that *B. pertussis* infections in adults are common and endemic, it has been suggested that an adult booster vaccination programme, using the newer acellular vaccines, might decrease the circulation of the organism in adults and that this might even lead to the elimination of the organism from populations [190].

# PNEUMONIA

DOUGLAS SEATON

The first part of this chapter discusses general aspects of pneumonia and its management. The second part discusses specific microbiological types of pneumonia as well as radiation pneumonitis and lipoid pneumonia. Pneumonia in the immunocompromised patient is covered in Chapter 52. Fungal, actinomycotic and nocardial causes of pneumonia are dealt with in Chapter 21, parasitic causes in Chapter 22, tuberculosis and other mycobacterial causes in Chapters 16–20. Drug-related inflammation of the lung is described in Chapter 37. The reader is referred to Chapter 9 for further information on antimicrobial agents.

## Definition

When the word 'pneumonia' is used in medical practice, it almost always refers to a syndrome caused by acute infection, usually bacterial, characterized by clinical and/or radiographic signs of consolidation of a part or parts of one or both lungs. However, the use of the term has been greatly extended to include non-bacterial infection of the lungs caused by a wide variety of microorganisms (Tables 13.1 & 13.2). Pneumonitis is occasionally used as a synonym for pneumonia, particularly when inflammation of the lung has resulted from a non-infectious cause, such as chemical or radiation injury.

## Epidemiological factors

Pneumonia accounted for approximately 198 deaths per 100 000 per year in England and Wales in 1997, and was the commonest infectious cause of death both in this country and the USA, being the sixth leading cause of all deaths in the UK and the USA [1–3]. Records from the early part of the twentieth century show a steady decline in the reported mortality from pneumonia that antedated the arrival of antibiotics. At around 1950, and coinciding with the beginning of the antibiotic era, the mortality rate levelled off and remained fairly constant. This mortality rate is heavily weighted against the elderly, so that death

rates were 35 and 21 per 100 000 for men and women respectively aged 55–64 years compared with 775 and 572 per 100 000 for those aged 75–84 years [1]. This predilection of pneumonia for the elderly is not new and led William Osler in 1898 to describe the condition as 'the friend of the aged', allowing them a merciful release from 'those cold gradations of decay that make the last state of all so distressing' [4]. Whereas pneumonia in the elderly is frequently a terminal event in a patient disabled or dying as a result of some other incurable disease, this is clearly not usually the case in younger previously healthy patient groups, such as military recruits or students, in whom mortality is low. Because pneumonia is caused by a variety of microorganisms of widely differing behavioural characteristics and antibiotic sensitivities, it presents a considerable challenge to the clinician, whatever the age group and whether or not there are important comorbid conditions.

The true incidence of pneumonia acquired in the community is unknown and undoubtedly many pneumonic episodes are treated by primary-care physicians as 'lower respiratory tract infection' or 'bronchitis' without recourse to chest radiographs. Overall estimates of the annual incidence of community-acquired pneumonia vary between 2 and 12 cases per 1000, being highest in infants and in the elderly [5,6]. Estimates for the USA run to 4 million cases annually with an attack rate of 12 per 1000 adults, causing 600 000 hospital admissions per year at a cost of \$23 billion [3]. The annual incidence of community-acquired pneumonia in those aged over 65 years has been estimated to be between 25 and 44 cases per 1000, with a rate varying from two to eight times greater than this in subjects of similar age but living in institutions such as residential or nursing homes [7,8]. Elderly patients are also much more likely to acquire pneumonia in hospital than are those belonging to younger age groups [9]. The subject of pneumonia in the elderly has been well reviewed [10]. Pneumonia is the most common hospital-acquired infection accounting for death, occurring with an estimated frequency of 0.5–5% of admissions [11].

In the relatively few countries of the world fortunate

enough to be able to afford a high standard of medical care, pneumonia in children is a problem that is dwarfed when comparisons are drawn with poorer countries. About 15 million children worldwide die each year as a consequence of acute respiratory infections, one-third of them from pneumonia, and 96% of these deaths occur in developing countries [12,13]. The infant mortality rate from pneumonia and influenza in Paraguay was found to be 30 times that in the USA [14]. Although there may be large differences in the incidence of childhood pneumonia between communities in rich and poor countries [15,16], the huge differences in mortality rates alluded to are more

likely to be explained by the lack of effective antimicrobial therapy and other supportive treatment [17,18].

Certain sections of the community, such as drug abusers, are susceptible to pneumonia. This may arise due to 'seeding' of the lung by staphylococci or other organisms from right-sided infective endocarditis [19], or as a result of the aspiration of oropharyngeal contents while in a stuporose state, which may result in a predominantly anaerobic or Gram-negative pneumonia (see Chapter 15 and Fig. 15.1).

The death rates from pneumonia may be influenced by seasonal factors, being greater in the cold winter months than in the summer. This difference is more evident in lower socioeconomic groups and is unaccounted for by influenza epidemics alone [20]. It is possible that greater overcrowding and poorer ventilation in cold weather may be factors enabling the spread of infection. In contrast, pneumonia due to *Legionella pneumophila* tends to occur more commonly in the warmer months.

As influenza epidemics (see Chapter 12) are associated with increased attack rates of pneumonia in adults, so respiratory syncytial virus (RSV) infection is complicated by pneumonia in infants and children, RSV infection tending to occur between November and February and influenza being mainly recorded between the end of December and March in the UK [21–26].

Population studies have shown that susceptibility to epidemics of pneumonia exists in communities where large numbers of individuals live in close contact with one another, for example gold miners in South Africa and long-house dwellers in Papua New Guinea. A study of an American Navajo Indian reserve showed an attack rate of 20 per 1000 inhabitants per year, of whom half required

hospital admission, these rates being highest in the very young and the elderly [27].

The largest decrease in incidence of pneumonia over the last 30 years has been in the infant population. The increased incidence in the elderly over the same period may be partly a consequence of the fact that two-thirds of all deaths now occur in hospitals compared with one-half 30 years ago and partly because hospital practitioners now certify the cause of death as ‘pneumonia’ more frequently than ‘heart failure’, as was their previous habit.

That knowledge of the method of coding disease has a crucial influence on the interpretation of available data is borne out by an apparent 55% reduction in the number of deaths from ‘bronchopneumonia’ and a 45% reduction in deaths classified as ‘pneumonia, unspecified’ in 1 year in the over-65 age group in England and Wales. This occurred when the Office of Population Censuses and Surveys issued new guidance to coders in 1984. Prior to that date the cause of death was always recorded from part 1 of the death certificate, whereas the new instruction, based on a World Health Organization rule, stated that where one of a range of conditions (including pneumonia) was the only cause of death mentioned in part 1 of the certificate, and a major disease was recorded in part 2, then the underlying *cause* of death should be taken from part 2 of the certificate [28].

Classification and terms in common usage

No categorization of pneumonia is entirely satisfactory (Table 13.3) but for descriptive purposes the classification should be both anatomical (the terms used communicate the extent and distribution of the process in the lung or lungs) and causal (the responsible microorganism is named). When, as is often the case, the infecting organism is not known it is useful in a predictive sense to consider

whether the pneumonia is community-acquired or hospital-acquired (nosocomial). It is also useful to consider whether the pneumonia may have resulted from overt pharyngeal aspiration and whether it is occurring in an immunocompetent or immunocompromised host. Finally, the workaday respiratory physician will recognize two sorts of pneumonia: that which is easy and responds to initial treatment and that which is difficult and fails to respond so that further investigation is required.

The anatomical terms used indicate whether the pneumonia involves one or more entire lobes or whether the process is confined to a segment or segments. In its most confined form, pneumonia may be subsegmental. Such anatomical descriptions are in life entirely dependent upon the chest radiographic appearances, which show the extent of pneumonia more accurately than can be gauged by physical examination. Early clinicians distinguished between bronchopneumonia and lobar pneumonia in pathological terms. Bronchopneumonia was regarded as a complication of bronchitis in which the patchy inflammatory process was confined to the territory of small or terminal bronchi and the lung lobules subtended by them, hence the alternative term ‘lobular pneumonia’. Lobar pneumonia, on the other hand, frequently occurred *de novo* in a previously healthy lung and was characterized by an inflammatory outpouring or exudation of fluid extending throughout most of a lobe or lobes [29].

It is commonplace for the term ‘lobar pneumonia’ to be used when there is clinical and radiographic evidence of confluent consolidation occupying the greater part of one or more lobes of one or both lungs. The term ‘segmental pneumonia’ is used when such consolidation is not extensive enough to occupy most of a lobe but corresponds more closely to the anatomy of a bronchopulmonary segment in one or more lobes. Where the area of radiographic shadowing is even more confined, then ‘subsegmental pneumonia’ is an appropriate descriptive term, although this still implies a confluent and localized process. Where subsegmental shadowing is patchy (non-confluent) and poorly localized, being scattered throughout part or the whole of one or both lungs, the term ‘bronchopneumonia’ remains entirely acceptable. Bronchopneumonia therefore tends to be multifocal and the pathologist commonly finds it to be bilateral and often basal [30].

This anatomical classification is complementary but subservient to a causal classification and is of only limited value in establishing the likely infective agent, for although lobar pneumonia is usually caused by *Streptococcus pneumoniae*, it can be caused by many other microorganisms besides, as indeed can all other anatomical types. Reasonable efforts should therefore be made to establish the identity of the pathogenic organism responsible for pneumonia in each patient in order that specific antimicrobial therapy can be directed against it, for without this

information some patients do not recover who otherwise would have done so.

The causal organism can only be guessed at when the patient is first seen and it is useful in this respect to classify the case as one of either community-acquired or hospital-acquired (nosocomial) pneumonia. These two groups are *not* mutually exclusive for particular pathogens but the spectrum of infecting organisms in the two groups does vary, partly because the hospital population has selected disproportionate numbers of elderly patients and those whose bacterial flora has been modified as a result of their stay as well as those whose immune defences are compromised by severe underlying disease or suppressed by drugs. Nosocomial pneumonia is a particular problem in postoperative patients and in those treated in intensive care units, the latter group being highly susceptible to lower respiratory tract infection [31–33]. The different lung pathogens found in hospitals result from the alteration in bacterial flora caused by the use of antibiotics and also often from the instrumentation or intubation of the upper airways of patients, which provides the organisms with easy access to the lungs. Such hospital-acquired infections are more frequently due to aerobic Gram-negative bacilli and *Staphylococcus aureus* (increasingly methicillin resistant) compared with those acquired in the community [34–36]. It is not uncommon for multiple organisms to be simultaneously involved in a single patient in intensive care units.

## Pathogenesis

Pneumonia is predisposed by any condition that (i) reduces or suppresses the cough, (ii) impairs mucociliary activity, (iii) reduces the effective phagocytic activity of alveolar macrophages and neutrophils, and (iv) impairs immunoglobulin production. Potential pathogens reach the lung to cause pneumonia chiefly by microaspiration of secretions containing oropharyngeal flora [37], but also by overt aspiration, by inhalation from the environment, from a nebulizer or anaesthetic circuit and by blood spread. Colonial organisms in an already diseased lower respiratory tract may also spread directly to cause pneumonia in previously unaffected lung; sometimes pathogens may spread directly from an adjacent extrapulmonary site of infection, such as the mediastinum, spine, chest wall or abdominal cavity.

## Aspiration and microaspiration

Aspiration of small amounts of oropharyngeal contents is known to occur in healthy people during sleep [38]. This tendency is increased by states in which the ability to cough is depressed or otherwise impaired (see Chapter 15), such as following surgery, general anaesthesia, tracheostomy, or the passage of an endotracheal or nasogas-

tric tube [39–42]. The intrinsic defences of the lungs may be unable to cope with the inoculum if it contains particularly pathogenic organisms or if there are sufficiently large numbers of less pathogenic organisms. Favourable conditions for infection may also be provided by chemical injury to the lungs resulting from overt gastric acid aspiration or by pulmonary oedema, and alcoholism is an important predisposing factor [43].

Many of the organisms that cause lower respiratory tract infections may exist commensally in the oropharynx. These include *Strep. pneumoniae*, *Haemophilus influenzae*, *Staph. aureus* and anaerobic bacteria, to name but a few. The oropharyngeal flora in hospital patients is often altered, with the presence of Gram-negative bacilli; hence the increased incidence of pneumonia caused by these organisms in such patients. Elderly patients in the community also tend to harbour a higher proportion of Gram-negative organisms in the oropharynx, so that this type of pneumonia tends to be more common in old patients both in and out of hospital [44,45]. It is also possible that mucosal ageing increases the ability of Gram-negative bacteria to attack the epithelial surface [46].

## Inhalation

The inhalation of microbes contained in small particle aerosols is thought to be important in the transmission of viral infections and also in *Legionella* pneumonia. The inhalation of infected particles from animals may be responsible for psittacosis and *Coxiella* pneumonia (Q fever). Oropharyngeal colonization followed by microaspiration is probably more important in other bacterial pneumonias, whereas patient-to-patient spread may occur by both direct contact (via fomites) and droplet spread. Pathogens may also be introduced to the lower respiratory tract by contaminated nebulizer circuits or other respiratory equipment, this route being avoidable by proper preventive measures [47,48].

## Colonization

The lower respiratory tracts of patients with pre-existing lung diseases, such as chronic bronchitis, emphysema, bronchiectasis and cystic fibrosis, may become colonized by potentially pathogenic organisms, which may cause acute exacerbations of infection, including pneumonic consolidation, from time to time [49].

## Blood spread

Occasionally, pneumonia may result from the haematogenous spread of bacteria from a focus of infection elsewhere. This may occur with Gram-negative and staphylococcal bacteraemia [50–52]. Patients with intravenous cannulae, temporary pacing wires and those

receiving chronic haemodialysis are particularly susceptible [53].

Investigation

Laboratory identification of infecting organisms

Laboratory investigation of a case of pneumonia should not delay treatment with antibiotics, the choice of which is based on a knowledge of the likely pathogens and an estimation of the severity of the infection (see p. 365). The lengths to which the clinician is prepared to investigate the microbiological cause of a case of pneumonia is likely to be determined by the severity of the illness at presentation (Table 13.4), its response to initial treatment and the laboratory facilities available. There are many investigational possibilities but a practical approach for community-acquired pneumonia is illustrated in Fig. 13.1.

Sputum microscopy

Laboratory examination of expectorated sputum remains the most commonly requested microbiological investigation in suspected lower respiratory tract infections. It remains useful, provided that samples are properly collected and promptly examined. Specimens that are clearly salivary should be discarded at the bedside to save labora-

tory time. Mucopurulent sputum is characteristic of bacterial pneumonias and bronchitis, but may also be found in viral pneumonia [55]. The adequacy of an expectorated sample may be judged microscopically in terms of the

Table 13.4 Markers of severity in pneumonia at initial assessment.

Altered mental state/confusion*
Tachypnoea $\geq 30$ breaths/min*
Hypotension, systolic $\leq 90$ mmHg, diastolic $\leq 60$ mmHg or need for vasopressors*
Arterial hypoxaemia $P_{aO_2} \leq 8$ kPa (60 mmHg) or $P_{aO_2} : F_{IO_2}$ ratio $\leq 33$ kPa (250 mmHg) on oxygen or need for $> 35\%$ $F_{IO_2}$ to keep $S_{aO_2} > 90\%$
Arterial hypercarbia $P_{aCO_2} > 6.5$ kPa (50 mmHg) or consideration of the need for mechanical ventilation
Chest radiograph shows more than one lobe involved or rapid progression
Evidence of renal insufficiency serum urea $\geq 7$ mmol/L* low urine output $< 20$ mL/h
Need for admission to intensive care unit

The risk of death has been found to increase over 20-fold when two or more of the features marked with an asterisk are present in the same patient (see text).

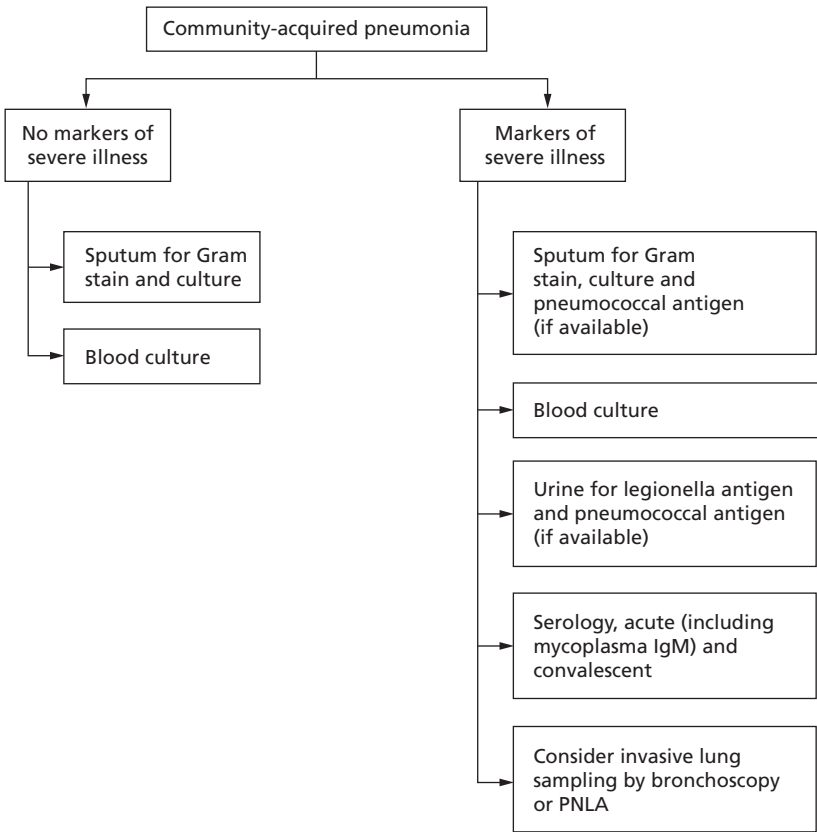

Fig. 13.1 Microbiological investigation of the patient admitted to hospital with community-acquired pneumonia (see text). PNLA, percutaneous ultra-thin needle lung aspiration (for those experienced with this technique). (After Finch & Woodhead [54].)

number of buccal epithelial cells present. Thus if 10 or more buccal squamous epithelial cells are noted per low-power ( $\times 100$ ) field, the specimen is likely to be salivary and unsuitable for culture [56]. Conversely, more than 25 neutrophils per low-power field indicate the presence of inflammation, although this may not apply to immunosuppressed patients. Similarly, a leucocyte to squamous epithelial cell ratio of greater than 5 may also be taken to indicate an adequate sputum sample rather than a salivary one.

Gram's stain may be helpful in identifying the cause when large numbers of one predominant type of organism are found in association with evidence of inflammation [57]. Less clear evidence of infection than the foregoing has to be interpreted cautiously since commensal organisms are likely to be picked up by sputum as it passes through the oropharynx [58]. Thus Gram-positive lancet-shaped diplococci suggest *Strep. pneumoniae*, Gram-positive cocci in clusters may be seen in *Staph. aureus* pneumonia, tiny Gram-negative coccobacilli suggest *H. influenzae*, numerous intracellular Gram-negative diplococci imply *Moraxella (Branhamella) catarrhalis* infection and larger Gram-negative bacilli suggest *Klebsiella pneumoniae* or other enteric pathogens. However, it should be noted that large numbers of Gram-negative bacilli have been found in sputum samples of patients on intensive care units without evidence of infection [59]. The absence of large numbers of organisms in an adequate sputum sample raises the possibility of *Legionella pneumophila*, *Mycoplasma pneumoniae*, *Coxiella burnetii* or a viral pneumonia. The application of routine Gram staining to sputum is an area of controversy, some experienced clinicians using it, others not [3,60].

The possibility of tuberculosis should never be forgotten and an acid-fast smear using either carbolfuchsin (Ziehl-Nielsen) or fluorochrome (auramine) should be requested when the chest radiographic appearances are compatible. False positives are rare and the smear provides early evidence of tuberculosis in about 50% of cases that are subsequently confirmed with positive cultures; positive smears are much more common when the radiographic changes are extensive and typical of active tuberculous infection [61]. Sputum may be induced with hypertonic saline in patients with suspected tuberculosis who are unable to raise secretions spontaneously; 20 mL of 2.7–5% saline is nebulized at a high flow rate and delivered by mask to the nose-breathing patient by a physiotherapist or other trained person, who then obtains the specimen and shepherds it to the laboratory in order to avoid more invasive procedures such as bronchoscopy.

Pathogenic fungi that may affect immunocompetent subjects (*Coccidioides immitis*, *Cryptococcus neoformans* and *Blastomyces dermatitidis*) can be detected under the microscope unstained on so-called potassium hydroxide 'wet-mount' preparations, as can *Aspergillus* spp. *Candida*

spp. are easily identifiable on a Gram stain, other fungi requiring specialized stains such as the Grocott-Gomori methenamine silver method. This last stain is also used to find the cysts of *Pneumocystis carinii*, being the most valuable *Pneumocystis* 'search stain', whereas the trophozoites require Giemsa or the quicker modified Wright-Giemsa (or 'Diff Quik') stains that may show them as minute dots in the alveolar spaces.

### Sputum immunodetection

Other tests sometimes applied to sputum include pneumococcal antigen detection (see below) by one of a number of possible methods, including latex agglutination, counterimmunoelectrophoresis (CIE), coagglutination or the Quellung reaction (p. 380) [62,63]. *Legionella pneumophila* is one of a number of organisms that may be detected rapidly in respiratory secretions by the direct immunofluorescent antibody test (DFAT). The specificity of this test for this organism is about 94% but the sensitivity is low at 50% [64]. Specific fluorescein-labelled monoclonal antibodies using the DFAT technique may also be used to detect *Chlamydia pneumoniae* in sputum and also *Pneumocystis carinii* in bronchoalveolar lavage fluid or induced sputum. An advantage of these tests is that their sensitivity is not reduced by the prior use of antibiotics.

### Sputum culture

The usefulness of standard sputum culture is limited by the delay, usually at least 24 h, between submission the specimen and receipt of a result. Culture also suffers from the same potential problem of contamination by oropharyngeal flora as does microscopy [65]. Furthermore, pathogens that were identified on the Gram stain may not grow in culture because of the prior use of antibiotics, which clearly reduces the sensitivity of culture techniques [66]. Where sputum samples have been found to be microscopically adequate (i.e.  $<10$  epithelial cells and  $>25$  neutrophils per low-power field), comparability with the positive yield obtained from transtracheal aspiration (see below and Chapter 8) has been claimed [56]. The sensitivity of sputum culture for pneumococci is about 50% [66].

The finding of *Escherichia coli* or *Proteus* spp., often reported as 'coliforms', usually implies an altered oropharyngeal flora as a result of antibiotic usage. *Klebsiella aerogenes* may be cultured for the same reason and is not a cause for concern; however, when the report is less specific, stating only '*Klebsiella* spp.' and if the patient is unwell, the laboratory should be asked to carry out further speciation so that pathogenic *Klebsiella pneumoniae* (the cause of Friedländer's pneumonia) or *Klebsiella ozaenae* (which may colonize areas of bronchiectasis) are not overlooked. *Pseudomonas aeruginosa* and *H. influenzae* may similarly colonize such lungs.

*Legionella* spp. may be cultured on a selective charcoal yeast extract medium if the patient is sufficiently ill to cause anxiety or if there are other grounds to suspect this organism. A result is relatively slow, taking about 3 days, and in the mean time further information may be forthcoming from DFAT on sputum, as mentioned above. Although culture of *Legionella* spp. is slower, it is more sensitive than DFAT and species other than *L. pneumophila* may be grown.

Fungal culture is not technically difficult and may be appropriate in certain clinical settings. The request for this is best made to the microbiologist in order to ensure that suitable media and incubation temperatures are used. The isolation of yeasts is common and usually results from oropharyngeal colonization, candidal pneumonia being an unusual accompaniment of severe immune compromise.

The microscopic and culture findings in sputum obtained by suction devices from patients who have an endotracheal or tracheostomy tube *in situ* are less reliable because the trachea rapidly becomes colonized by Gram-negative organisms once the tube has been placed and these organisms need not be representative of infection in the lung itself. Precautions have been described to reduce the contamination of such samples and, more recently, quantitative culture techniques have been developed as outlined in the next section [67].

#### Invasive methods for obtaining respiratory secretions

Other methods for obtaining respiratory secretions are more invasive and may be associated with morbidity. Their use is therefore confined to patients who are severely ill and in whom it is considered important to identify the organisms rather than relying on an initial empirical antimicrobial approach or in whom such an approach has already been tried and failed. Any specimens so obtained should be submitted for microscopy (e.g. Gram and Giemsa stains to detect intracellular and extracellular organisms in the lower respiratory tract) and culture, as well as for the immunological and other tests mentioned in these sections, depending upon local availability. It has been shown that these severe infections may be polymicrobial and that the mortality is almost doubled in such cases [68].

Transtacheal aspiration may be carried out in patients who are unable to raise sputum or in whom the response to the chosen antibiotics is poor. This technique has been discussed in detail in Chapter 8 but is now rarely used. The success of the procedure relies on the assumption that the tracheobronchial tree below the larynx is sterile, but false-positive results occur in patients with chronic lung disease because of tracheobronchial colonization [69]. The technique has also been applied when anaerobic lung infection is suspected.

Fibreoptic bronchoscopy (see Chapter 8) picks up oropharyngeal contaminants unless special precautions are taken using a protected specimen brush (PSB). The preservative in the local anaesthetic may also have a significant antibacterial effect [70,71]. The PSB may be combined with, or used separately from, bronchoalveolar lavage (BAL) to obtain quantitative cultures in order to discriminate between the presence and absence of pneumonia, usually on ventilated patients in an intensive care setting [72,73]. The diagnostic threshold for pneumonia, rather than airway colonization, has been reported as  $10^3$  cfu/mL (colony forming units per millilitre) in respiratory secretions obtained by PSB, which yields only 0.01–0.001 mL of material. On the other hand, BAL subtends a wide area of tissue and lung secretions are diluted between 10 and 100-fold, so that when interpreting results a threshold of  $10^4$  or  $10^5$  cfu/mL may be taken [74,75]. By combining PSB and BAL and by counting intracellular organisms, Chastre and colleagues [74] claimed a sensitivity of 100% (compared with 86% for either technique alone) and a specificity of 96%. Bronchoscopy can therefore provide clues in the difficult case when other methods have failed, even when the picture has been clouded by the almost inevitable prior use of antimicrobials. Infection with less usual organisms, such as *Legionella* spp., *Mycobacterium tuberculosis*, *Pneumocystis carinii*, other fungi or anaerobes, may also be detected in such cases as well as the occasional unsuspected predisposing cause like the mechanical narrowing of a bronchus [76,77]. On the other hand, negative results have to be treated with caution in patients already receiving antimicrobial therapy, since they may indicate either that the antibiotics were appropriate and that the organisms have been suppressed or that there was no infection there in the first place and that the infiltrate was due to a non-infective cause, as may be so in over 40% of cases [78].

Percutaneous ultra-thin needle lung aspiration without fluoroscopic guidance has obtained a positive culture rate of about 60% in non-ventilated patients with hospital-acquired pneumonia in one recent study [79]. A previous positive microbiological diagnosis had been made non-invasively in less than 10% of these patients and the investigation resulted in a change in antimicrobial therapy in 30% of cases, being complicated by shallow pneumothoraces in 3% of patients [79]. Higher complication rates and lower yields have been reported in earlier studies [80,81]. The success rate of ultra-thin needle aspiration is dependent upon the experience of the operator, the size of the infiltrate and its proximity to the pleura. It is reduced by prior antimicrobial therapy but enhanced if a pneumococcal antigen-detecting technique is applied to the aspirate [82,83]. The technique uses a 25-gauge needle and is discussed in Chapter 8.

These invasive techniques have mainly been used in research settings and their wider clinical role remains

undecided and somewhat controversial. The bronchoscopic option in immunocompetent patients may be appropriate once they have reached the stage of intubation and mechanical ventilation. A simpler option in the intubated and ventilated patient is the quantitative culture of endotracheal aspirates. When a threshold of  $10^6$  cfu/mL is used, this technique has been found to have a sensitivity of 68% and a specificity of 84% [84]. This will miss one-third of cases with pneumonia and compares less favourably with PSB and BAL either separately or together but is nevertheless an option if bronchoscopy is not readily available. A further quantitative culture technique that has been developed uses a protected telescoping catheter and has produced results approaching those obtained with the bronchoscopic methods [85,86].

Transbronchial, thoracoscopic or open lung biopsies tend to be reserved for diffuse pulmonary infiltrates of undetermined cause and, in the context of suspected infection, are occasionally carried out in sick immunocompromised hosts including transplant recipients, those receiving chemotherapy for lymphoma and in patients with AIDS, in whom the presence of an unusual opportunist pathogen is likely and in whom less invasive diagnostic approaches like BAL have failed to identify the cause (see Chapter 52) [87–92].

### Blood culture

It is normal practice to carry out blood culture on all patients admitted to hospital with suspected pneumonia since a positive culture may occur in 10–30% of cases, the higher percentage applying to pneumococcal pneumonia. This provides definitive proof (i.e. high specificity) of a pathogenic organism, often lacking where sputum culture and other tests are concerned, and is also of prognostic importance because bacteraemia is a marker of a more severe infection. However, a recent retrospective study of 517 immunocompetent patients with community-acquired pneumonia found positive blood cultures in only 6.6%, with an antibiotic change based on the culture occurring in only 1.4% [93]. The implication of this is that appropriate antimicrobial therapy will be initiated on empirical grounds in nearly all cases before the results of blood cultures are available.

### Pneumococcal antigen detection

Pneumococcal antigen detection using latex agglutination (sputum, blood) or, less commonly, CIE (sputum, urine, blood) is carried out routinely in some centres but is impractical for all patients, being usually reserved for those who are severely ill. CIE depends upon the migration of pneumococcal antigen and of antibody from two wells cut in an agarose-coated slide when an electric field is placed across it. Where the two meet they react and form

a precipitin line. Pneumococcal antigen detection may produce a result within 1 h. It has been found to be less sensitive when applied to blood (<25%) than urine (about 40%), being most sensitive when used on mucopurulent sputum (about 80%) [94,95]. This compares with a sensitivity of about 50% when the Gram stain is applied to sputum for the same purpose. The investigation can also be applied to pleural fluid and to lung secretions obtained invasively (ultra-thin needle aspiration and BAL), so that the sensitivity of these tests may be increased [96–98]. The specificity of sputum pneumococcal antigen for detecting cases of pneumococcal pneumonia is reduced to about 70% because *Strep. pneumoniae* is often isolated from the sputum of patients with chronic bronchitis who do not have pneumonia. A positive sputum pneumococcal antigen test may also not differentiate between oropharyngeal colonization and pulmonary infection; furthermore some capsular antigens are difficult to detect by these methods. Pneumococcal antigen testing has been useful in research to establish the relative frequencies with which different organisms are found in population studies of pneumonia, since its sensitivity is not reduced by the prior use of antibiotics, but it has not established itself as a routine test in most general hospital laboratories. It has the advantage of providing rapid information and might be usefully applied in the sicker patient in whom routine cultures are likely to have been suppressed by previous treatment with a broad-spectrum antibiotic. Pneumococcal antigen may be detected in the serum or urine of 50% of patients with pneumococcal pneumonia who are non-bacteraemic in terms of negative blood cultures. The antigen remains detectable for 7–14 days after bacteraemic pneumococcal pneumonia.

### Standard acute and convalescent serological testing

The usual serological tests involve the measurement of complement-fixing antibody levels in the blood, although more sensitive enzyme-linked immunosorbent assay (ELISA) and immunofluorescent tests are tending to replace them. Serological tests may be used for infections caused by *Mycoplasma pneumoniae*, *Chlamydia* spp., *Coxiella burnetii* and *Legionella* spp. By its nature, the complement fixation test (CFT) is seldom of immediate value and when positive usually provides diagnostic information retrospectively, as two paired samples are required in order to demonstrate a fourfold rise or fall in the titre of specific antibodies. It is usual to wait about 14 days between the two samples, although in some infections, such as *Mycoplasma*, a rise may be detected earlier; in others, notably *Legionella*, the rise may take several weeks. A single titre greater than 256 is suggestive of infection and if information on an unpaired sample is needed, the laboratory should be informed to discourage them from storing it until the second sample materializes. The problem with

paired sampling is that the results are likely to come too late to be of clinical relevance. For *Mycoplasma pneumoniae*, both IgG and specific IgM titres may be measured by ELISA. High IgG titres may persist for over a year but a raised titre of *Mycoplasma*-specific IgM is consistent with acute infection and is said to be positive in about 70% of patients admitted to hospital with this infection [99]. When *Mycoplasma* is suspected, cold agglutinins should be looked for and are present in over 50% of cases; this may be easily done on the ward by cooling a tube of the patient's citrated blood to about 4°C in a refrigerator (see p. 394). For *Legionella* both the rapid microagglutination test (RMAT) and indirect immunofluorescent antibody test (IFAT) are widely available (see section on *Legionella* pneumonia).

### Newer microbiological technologies

The tantalizing promise of new methods for the rapid detection and identification of specific organisms using molecular genetic techniques seems close to being fulfilled but for most laboratories and clinicians has yet to be delivered, largely because of financial constraints. DNA probes have been developed for characterizing target organisms and minute amounts of target DNA can be amplified by the polymerase chain reaction (PCR) to improve the chance of their detection by the DNA probe so that the sensitivity of the test is increased. A PCR assay has recently been tested on the serum of patients with bacteraemic pneumococcal pneumonia and was found to have a sensitivity of 100% and a specificity of 94% [100]. Similar probes have been, or are being, developed for a wide range of organisms including *Legionella pneumophila*, *Mycoplasma pneumoniae*, *Neisseria meningitidis*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Coccidioides immitis*, *Mycobacterium tuberculosis*, *Mycobacterium avium* complex and *Mycobacterium kansasii* [101]. Thus the identification of a mycobacterial infection may take hours rather than weeks, although the organism still requires culture in order to allow antimicrobial sensitivities to be confirmed.

### Pleural fluid

If a pleural effusion is present in a patient suspected of having pneumonia, it should always be examined to exclude an empyema (see Chapter 14). Gram and acid-fast stains may be useful. The culture of pathogenic organisms, assuming a clean technique, is always significant and valuable. When the diagnosis of pneumonia is in doubt, a pleural biopsy should be carried out as described in Chapter 8. Pleural biopsy is also routine if a tuberculous effusion is suspected, one specimen being submitted unfixed for culture and the remainder being sent for histology in the usual way. Tuberculous pleural effusions are predominantly lymphocytic, whereas the finding of a predominance of neutrophil leucocytes is suggestive of non-

tuberculous bacterial infection, the protein content being that of an exudate in both cases (see Chapter 43). Some biochemical findings (low pH, high lactate dehydrogenase, low glucose) have been used to predict which parapneumonic effusions may be likely to develop into empyemas (see Chapter 14) [102].

### Chest radiography

An abnormal chest radiograph is a *sine qua non* in pneumonia, providing an immediate visual impression of the extent of involvement. The clinician can, at best, make an informed guess about the likely microbiological cause of pneumonia on the basis of the radiographic findings but as so much overlap occurs between one organism and another, this approach is often inaccurate. It is emphasized that almost every causative agent can produce a wide variety of different radiographic appearances, so that it is unwise to assume that a confluent lobar pneumonia is bound to be caused by *Strep. pneumoniae* despite the probability that this is the case. Similarly, cavitation need not be due to *Staph. aureus* pneumonia but may occur in necrotizing Gram-negative pneumonias, such as those caused by *Klebsiella pneumoniae*, or pneumonia arising from the aspiration of anaerobic bacteria or even from infection with *Strep. pneumoniae* when serotype 3 is involved.

Radiographic response to treatment usually lags well behind clinical improvement and pneumococcal pneumonia may take 6 weeks to clear on the chest film [103]. Persistent, recurrent or worsening shadowing may indicate either inappropriate treatment or bronchial obstruction by a foreign body or, more commonly, tumour particularly in patients over the age of 60 years [104].

### Arterial oxygen saturation and blood gas analysis

Oxygen saturation as a screen followed by arterial blood gas analysis when desaturation is evident should be carried out in order that hypoxaemia may be corrected and to help gauge the severity of the infection. The need for an inspired oxygen of 35% or more to maintain the oxygen saturation above 90% implies severe pneumonia; so does a  $P_{aO_2}$  of 8 kPa (60 mmHg) or less or a  $P_{aCO_2}$  of 6.5 kPa (50 mmHg) or more. These findings warn that assisted ventilation may become necessary.

### Other laboratory findings

The white cell count is frequently raised in bacterial pneumonia, with a neutrophilia. Elderly patients are not always able to mount such a response. Sometimes when sepsis is overwhelming there may be a leucopenia. A lymphocytosis may occur in viral infections or in those due to 'atypical' organisms, such as *Chlamydia*, *Coxiella* or

*Mycoplasma*. The white count may be normal in viral pneumonia. The detection of cold agglutinins is discussed under standard serological testing (above) and under the later section on *Mycoplasma pneumoniae* (p. 394).

Numerous non-specific biochemical abnormalities have been noted, such as a raised blood urea, bilirubin, transaminases and alkaline phosphatase. Hypophosphataemia may also occur [105]. Hyponatraemia due to inappropriate antidiuretic hormone (ADH) secretion may occur in any pneumonia and is notably more common in *Legionella* infection.

Urinalysis may detect small amounts of protein and both red and white blood cells may be seen on microscopy in pneumonia. These findings are of no discriminatory value and may occur in any systemic infection. As mentioned above, pneumococcal antigen may be detected in urine more frequently than in blood but less frequently than in sputum. *Legionella* antigen may also be detected in urine by ELISA, indicating *L. pneumophila* type 1 infection (thought to account for about 80% of human legionellosis), and this test is well worth doing for a rapid answer in severely unwell patients with pneumonia.

## Antimicrobial treatment

A provisional diagnosis of pneumonia is generally based on the history of an acute febrile illness associated with a cough usually productive of mucopurulent sputum, physical findings suggestive of consolidation and consistent chest radiographic appearances. More often than not in general hospital practice some or most of the classical features of pneumonic consolidation are not elicited by the resident medical staff, who initiate treatment on the basis of probable 'lower respiratory tract infection'. Frequently a patient has received an antibiotic prior to hospital admission and this may make microbiological identification of the infecting agents more difficult, as alluded to above; nevertheless blood cultures should be taken routinely and sputum obtained expeditiously if it is readily available (Fig. 13.1) before commencing or continuing antibiotic treatment on what is perforce empirical grounds, at least initially. However, antibiotics should *not* be delayed if a sputum specimen cannot be immediately obtained. Such empirical treatment is acceptable and entirely necessary and has been enshrined by the production of so-called 'guidelines', which are simply statements of what the authors were prepared to sign up to as good clinical practice for the population they were considering at the time of writing [106–111]. Empirical therapy of this sort is not without problems, being based on epidemiological data or large case series, so that recommended regimens may apply to one population but not another. Furthermore, a mechanism for regular review should ideally be in place to take account of changing patterns of disease, such as the reduced susceptibility of common

organisms to standard antibiotics (e.g.  $\beta$ -lactamase producers), the increasing incidence of certain organisms in susceptible sections of the population (e.g. *Pneumocystis carinii* pneumonia in human immunodeficiency virus, HIV, infection) and the emergence of 'new' or previously unrecognized organisms (e.g. *Legionella* in the 1970s and more recently *Chlamydia pneumoniae*). Guidelines should not be taken as entirely prescriptive and it is up to the responsible clinician to be prepared to deviate should the circumstances of the individual case require this.

## Outpatient treatment

Milder cases of pneumonia may be managed out of hospital; in the UK, many patients are treated by their family practitioner for 'lower respiratory tract infection' and respond without even coming to chest radiography. Most cases (85–90% in the UK), particularly in younger ( $\leq 60$  years) and previously healthy patients, are due to pneumococcal infection [112] and respond well in most geographical locations to an aminopenicillin such as amoxicillin (amoxycillin) 250–500mg three times daily, which is cheap, well tolerated and a reasonable first choice for oral therapy in subjects not known to be allergic to penicillin. Those who do not respond and who are still not ill enough to require admission require a change in tactics. They may have *Mycoplasma pneumoniae* infection (see p. 392), particularly in epidemic years, in which case they respond if their treatment is switched to a macrolide such as erythromycin, this class of drug also containing the antibiotics of first choice in penicillin-allergic patients. The knowledge that erythromycin is also usually effective against the pneumococcus led the authors of the American and Canadian guidelines to recommend its use as the first-line antimicrobial in this category of patient [60,113]. However, some pneumococci (approximately 9% in the UK) are resistant to erythromycin [114,115]; also since these initial guidelines were written, newer (and more costly) macrolides have become available, clarithromycin 250mg twice daily being as effective as erythromycin 500mg four times daily as well as causing less nausea, with the likelihood of better outpatient compliance [116]. Azithromycin has a half-life of over 40h, allowing once-daily dosage, and has been recommended as a 3-day course for infective bronchitis and is apparently also effective in pneumonia [117]. It is concentrated very well intracellularly, with low blood levels, so that there are some theoretical reservations about its effectiveness in potentially bacteraemic pneumococcal infection [118,119]. When considering whether to cover for atypical pathogens such as *Mycoplasma*, *Chlamydia*, *Coxiella* and *Legionella* in non-severe pneumonia, it should be borne in mind that a large meta-analysis covering over 33000 patients found such atypicals to account for only 2.9% of infections [120].

Those patients who fail to respond to amoxicillin or a macrolide are frequently older and often have coexisting lung disease, such as chronic bronchitis and emphysema. The resistant pathogens in such patients are not infrequently  $\beta$ -lactamase-producing *H. influenzae* or *Moraxella catarrhalis*. Resistance rates for *H. influenzae* against ampicillin/amoxicillin in the UK are around 5% of isolates, although levels of over 15% have been recorded in certain districts, with higher rates in the USA [121], so that it is essential to be informed about the sensitivity patterns in one's own locality. *H. influenzae* is also commonly resistant to erythromycin, although less so to the newer macrolides such as clarithromycin. These resistant cases can often be treated successfully with an orally administered  $\beta$ -lactam-stable antibiotic, such as an aminopenicillin, combined with a  $\beta$ -lactamase inhibitor, e.g. amoxicillin/clavulanate (co-amoxiclav) or ampicillin/sulbactam (in the USA). Alternative oral  $\beta$ -lactam-stable antibiotics that may be used in this situation include second-generation (e.g. cefaclor) or third-generation (e.g. cefixime) cephalosporins. Fluoroquinolones such as ciprofloxacin or ofloxacin are also very effective against *H. influenzae* and *Moraxella catarrhalis*, the latter being given once daily. However, this group should *not* be used as first-line therapy because of their relatively poor *in vivo* activity against the pneumo-

coccus [122], although newer members such as spar-floxacin may be more successful in this regard. A scheme of treatment is illustrated in Figs 13.2–13.4. Duration of empirical treatment is ordinarily 1 week.

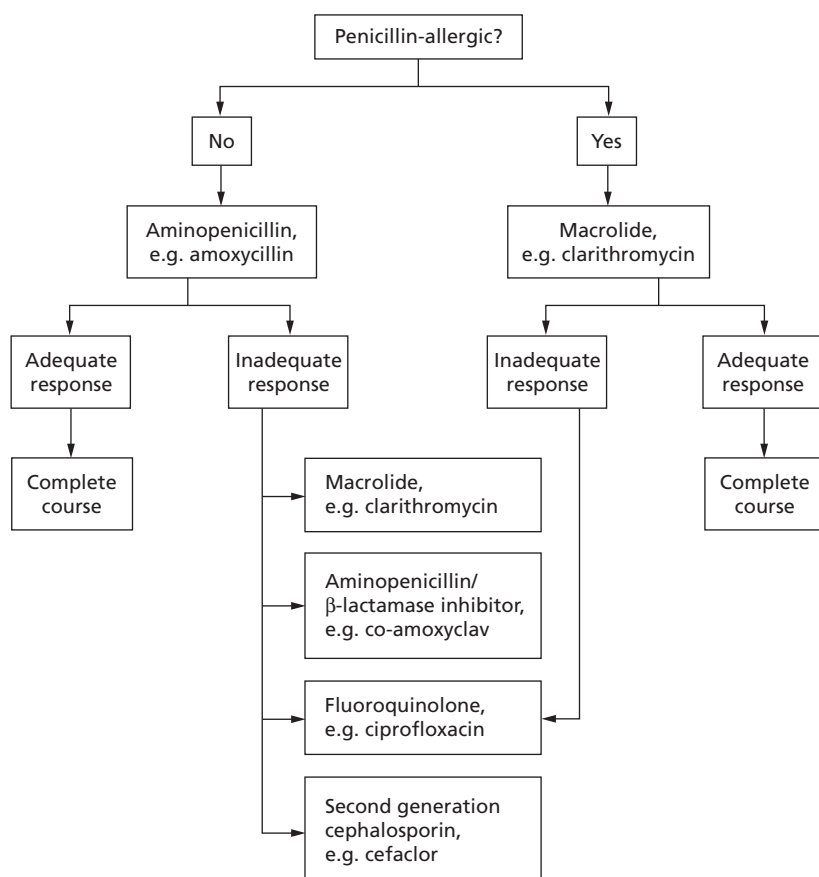

### Inpatient treatment of community-acquired pneumonia

#### Factors influencing initial antimicrobial treatment

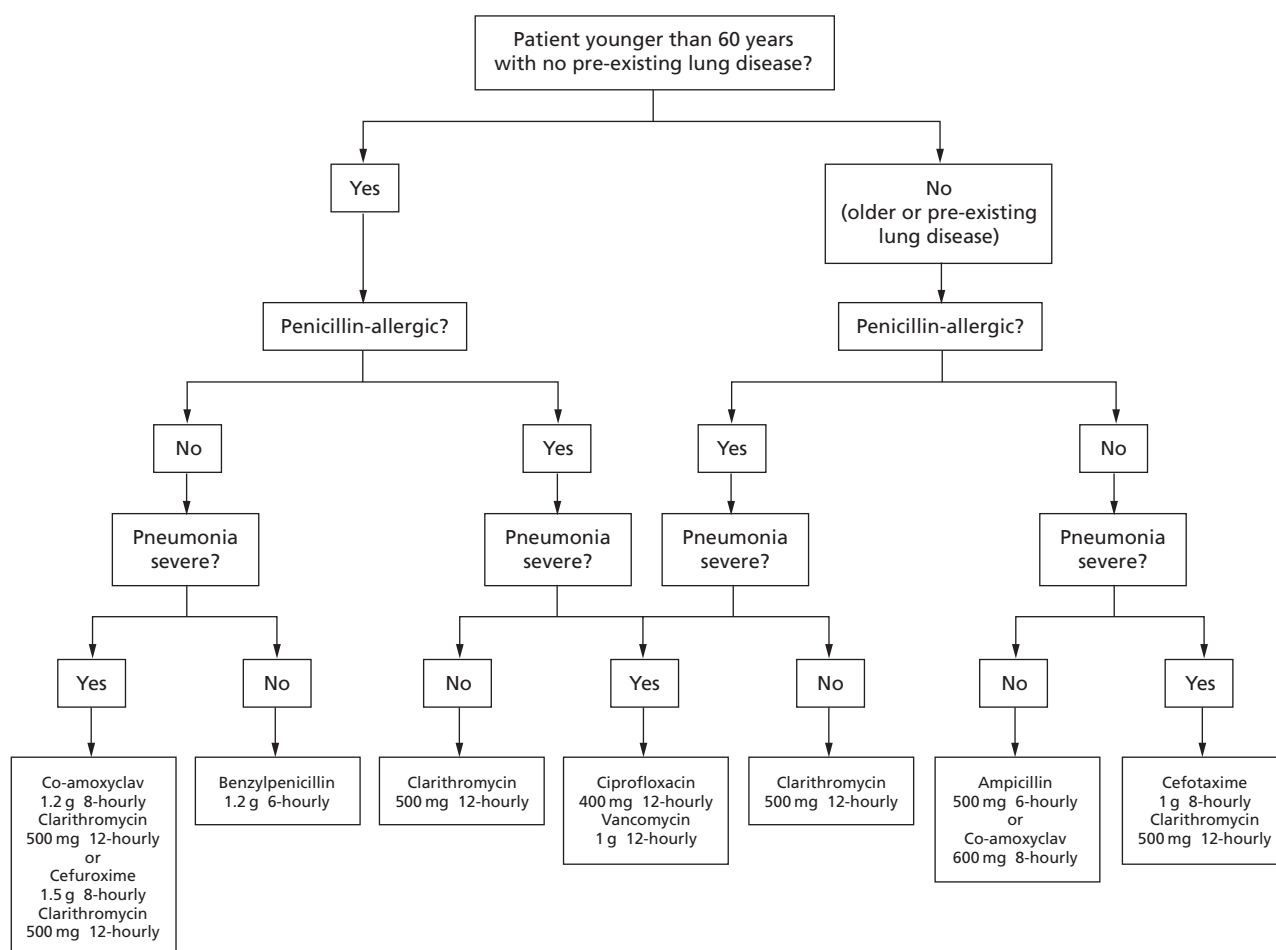

Patients admitted to hospital from the community with pneumonia are likely to be iller and often receive intravenous antimicrobial treatment at first. The initial choice of antibiotic regimen should be influenced by:

- 1 whether the infection is judged to be severe or not;
- 2 the presence of comorbid disease;
- 3 the patient's age;
- 4 antimicrobials already received in the community.

An early estimation of the severity of the infection is an important consideration in determining initial antibiotic cover (see below and Table 13.4, p. 360) [60,109]. The possible consequences of missing the responsible pathogen in a very ill patient is obvious and cover must therefore be broad, whereas in a patient who is less sick failure to respond to a first-line antibiotic can lead to a change in

**Fig. 13.2** An empirical orally administered antimicrobial approach for mild pneumonia treated in the community (see text).

**Fig. 13.3** An empirical intravenously administered antimicrobial approach for the initial treatment of hospital-acquired pneumonia in hospital (see text).

therapy. It is a good principle to keep the antimicrobial spectrum as narrow as clinical circumstances allow and, where effective choices exist, to consider the cost.

The presence of certain comorbidities will focus the physician's attention on the increased probability of particular organisms or groups of organisms. Examples are those associated with overt oropharyngeal aspiration (see section on aspiration pneumonia, p. 412), with immunosuppression (see Chapter 52) and with spread from elsewhere, e.g. following recent bowel surgery. When the patient has chronic lung disease, such as emphysema, chronic bronchitis or bronchiectasis, the initial choice of antibiotic may also be influenced by a knowledge of likely colonists such as *H. influenzae* or of previous microbial isolates, such as *Moraxella catarrhalis* or *Ps. aeruginosa*, in earlier infective exacerbations. The treatment of infection in cystic fibrosis is another such case and is discussed in Chapter 30.

Finally, with the increasing prevalence of  $\beta$ -lactamase-producing pathogens and the development of other forms

of resistance, some knowledge of local patterns of microbial susceptibility to those antibiotics in common use is helpful.

#### Assessment of severity in community-acquired pneumonia (Table 13.4, p. 360)

It will come as no surprise that universal agreement on the definition of severe community-acquired pneumonia has not been reached. This is largely because comparisons between different studies are not always easy, bearing in mind the many different clinical settings and methodological approaches that have been reported. However, a number of seemingly valid observations can be made. First, the patient who shows outward signs of respiratory distress is at increased risk of dying [35,123–125]. These signs include tachypnoea with a respiratory rate upwards of 30 breaths/min, especially if the patient has altered cerebration with drowsiness or confusion [124,126]. Clearly such a patient is likely to be hypoxic and cyanosed; indeed the finding of a  $P_{aO_2}$  of less than 8 kPa (60 mmHg) when the patient is breathing room air is accepted as a marker of severity, as is hypercarbia [60,109]. By the time

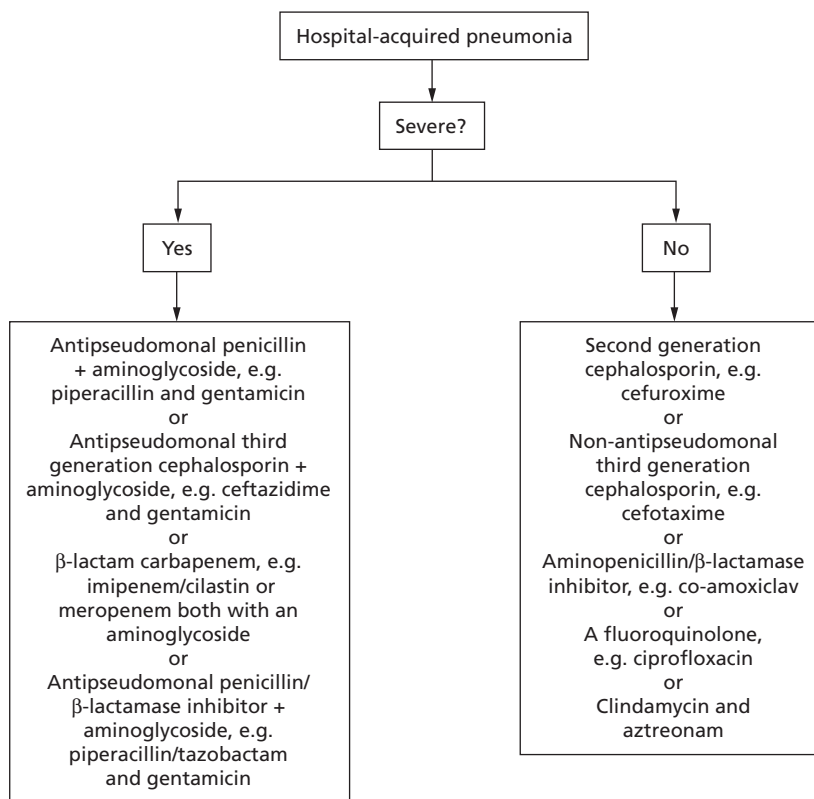

Fig. 13.4 An empirical approach for the treatment of hospital-acquired pneumonia (see text).

these measurements have been made many patients are receiving supplemental oxygen already, in which case the ratio of arterial oxygen tension to fractional inspired oxygen concentration has been used, a  $P_{aO_2}/F_{IO_2}$  ratio equal to or less than 33 kPa (250 mmHg) having the same significance [60]. Cardiovascular compromise as evidenced by hypotension is also prognostically serious, with systolic and diastolic blood pressures equal to or less than 90 and 60 mmHg (12 and 8 kPa) respectively being prognostically serious [35,109,123]. Evidence of renal impairment, with even a modest increase in the serum urea to 7 mmol/L or greater, has also been found to increase the chance of mortality, particularly when combined with tachypnoea and hypotension; indeed the risk of death was found to increase over 20-fold when two or more of the features marked with an asterisk in Table 13.4 were present in the same patient [35,123,127]. Radiographic evidence of involvement of both lungs or more than one lobe of lung or a worsening radiographic picture within the space of 48 h is also of prognostic significance and alerts the physician to a serious situation [60,128]. A marked leucocytosis ( $>30 \times 10^9/L$ ) or leucopenia ( $<4 \times 10^9/L$ ) has also been found to be associated with a poorer prognosis [4]. Patients with severe pneumonia may deteriorate rapidly so that they require close monitoring and active management, which can often be most easily provided in an intensive care or high-dependency unit. The following

recommendations, based on age, the presence or absence of underlying lung disease and a determination of severity, offers a practical approach likely to be effective and are condensed in Fig. 13.3.

### Community-acquired pneumonia in younger, previously healthy patients

#### Non-severe infection

It is recommended that a younger (<60 years) and previously healthy patient who is ill enough to be admitted to hospital with community-acquired pneumonia, who has no suggestion of immunosuppression or other risk factors but who is not severely ill according to the criteria outlined above should be treated initially with intravenous benzylpenicillin 1.2 g 6-hourly. In common practice an intravenous aminopenicillin (ampicillin/amoxicillin) 0.5–1 g 6-hourly is often used instead, but this should not be necessary as *H. influenzae* and *Moraxella catarrhalis* are unlikely to be implicated. It is also common practice to add a macrolide, although this too is not necessary unless the patient is judged to be sufficiently ill, unless the admission occurs during a *Mycoplasma pneumoniae* epidemic or unless there are features to make the clinician suspicious of *Legionella* infection (see p. 385) [129]. Those available include erythromycin 0.5–1 g 6-hourly, clarithromycin

500mg 12-hourly or azithromycin 500mg once daily, the newer macrolides being better tolerated (less nausea) and requiring less frequent administration but being more expensive than erythromycin.

The first choice is based on the probability of the infection being caused by *Strep. pneumoniae* [35], for which benzylpenicillin is still the most effective antibiotic in most geographical locations (minimum inhibitory concentration, MIC, usually <0.06 mg/L); the choice of a macrolide is based on the possibility that the pneumonia might be caused by *Mycoplasma pneumoniae* or *Legionella pneumophila* [35]. The more infrequent causes of pneumonia such as *Chlamydia pneumoniae*, *Chlamydia psittaci* and *Coxiella burnetii* are also covered by macrolides, which tend to accumulate within tissues and hence their effectiveness against these intracellular 'atypical' pathogens. A macrolide alone, particularly a newer one, would probably be effective against *Strep. pneumoniae* as well but blood levels are not as high and the potentially bacteraemic pneumococcus is likely to be eradicated more effectively by benzylpenicillin if this can be used. Other organisms, such as *H. influenzae*, *Moraxella catarrhalis*, Gram-negative enteric bacilli and anaerobes, are unlikely to be implicated in this category of patient and antimicrobial cover for them should not ordinarily be required.

A history of penicillin allergy in a non-severe case requires the omission of benzylpenicillin and inclusion of a 'stand-alone' macrolide, although increasing resistance rates to erythromycin are being reported for the pneumococcus so that occasional treatment failures might occur with this class of drug [114,115,130,131]. Alternatively and if the history of 'allergy' is not severe, consisting at worst of an uncomplicated rash rather than angio-oedema or anaphylaxis, then it is entirely reasonable to use a second-generation cephalosporin, such as cefuroxime, initially.

As soon as it is clear that the patient is responding, antimicrobial treatment may be switched from the parenteral to the oral route, usually by means of an aminopenicillin (with or without a  $\beta$ -lactamase inhibitor) or macrolide; indeed some might use oral treatment from the start. Uncomplicated pneumonia is usually treated for 1 week. Longer courses of treatment are conventional for *Legionella* and *Chlamydia* pneumonias.

### Severe infection

Should the patient appear severely ill from the start or fail to respond to initial treatment, then the antimicrobial spectrum must cover *Legionella* with a macrolide as above and should be broadened by the inclusion of antistaphylococcal cover. Approaches include (i) the use of co-amoxiclav 1.2g i.v. 8-hourly and a macrolide, which as well as covering the pneumococcus and *Legionella* also provides some cover for methicillin-sensitive *Staph. aureus* through amoxicillin/clavulanate

and (ii) the use of cefuroxime 1.5g i.v. 8-hourly and a macrolide, which as well as covering the pneumococcus and *Legionella* also provides some cover for methicillin-sensitive *Staph. aureus* through cefuroxime. The alternative use of benzylpenicillin to cover the pneumococcus effectively, a macrolide to cover *Legionella* and other 'atypicals' and flucloxacillin to provide cover for methicillin-sensitive *Staph. aureus* is also likely to be effective but fails to cover the unusual case of *H. influenzae* or other Gram-negative pneumonia.

Where it has been decided that methicillin-sensitive *Staph. aureus* is the probable major pathogen, it is usual practice to direct two antibiotics against it; thus the antistaphylococcal effect of flucloxacillin 1–2g 6-hourly i.v. can be supported by rifampicin 600mg 12-hourly i.v. or orally, this also being a potent antistaphylococcal antibiotic. Options for the penicillin-allergic patient include clindamycin, vancomycin and (provided the allergy is not severe) cefuroxime, all of which may be combined with rifampicin. Suspicions of staphylococcal infection may be heightened by the occurrence of severe pneumonia in seasons of the year when influenza infection is common (winter and early spring) or by the appearance of cavitation on the chest radiograph. Similarly for *Legionella* pneumonia, rifampicin is often added to a macrolide for increased effect when this infection is confirmed in the laboratory. An alternative approach is required when methicillin-resistant *Staph. aureus* (MRSA) is suspected or confirmed (see p. 405).

The American Thoracic Society guidelines recommend cover for Gram-negative enteric bacilli including *Ps. aeruginosa* in patients with severe pneumonia from the start [60]. Infection with this latter organism has been associated with a high mortality [132]. However, there is some evidence to suggest that the majority of such isolates occur in association with underlying structural lung disease such as bronchiectasis [81]. The author does not regard this approach as necessary in the initial treatment on medical wards of the younger previously healthy patients under discussion in this section, with the caveat that admission and mechanical ventilation on an intensive care unit for more than a few days can be expected to result in recolonization of the upper respiratory tract with Gram-negative enteric bacilli with the potential for nosocomial pneumonia.

A past history of *serious* penicillin allergy in a case of severe pneumonia is unusual but requires the omission of these agents and other  $\beta$ -lactam antibiotics. The use of vancomycin (Gram-positive cocci) and ciprofloxacin (*Legionella* and other 'atypicals') is one option; clindamycin (Gram-positive cocci) with a macrolide such as clarithromycin (*Legionella* and other 'atypicals') is another. If as is much more common, the history of 'allergy' is not severe, consisting at worst of an uncomplicated rash rather than angio-oedema or anaphylaxis, then it

is entirely reasonable to add a cephalosporin such as cefuroxime to the macrolide in order to provide some cover for methicillin-sensitive *Staph. aureus*.

Again, the switch from parenteral to oral treatment is made as soon as possible and uncomplicated pneumonia is usually treated for 1 week. Longer courses of treatment are conventional for *Legionella*, *Chlamydia* and often staphylococcal pneumonias.

### Community-acquired pneumonia in older patients and those with chronic lung disease

Irrespective of the severity of infection, the spectrum of antimicrobial cover should be broadened beyond benzylpenicillin in patients with chronic lung disease, including those with chronic bronchitis due to previous tobacco smoking, and also in older (>60 years) previously healthy subjects admitted to hospital with community-acquired pneumonia. Those organisms that might be encountered in younger previously healthy patients (see above) should still be anticipated but increased consideration needs to be given to *H. influenzae*, *Moraxella catarrhalis* (usually occurring in purulent bronchitis rather than pneumonia) and to a lesser extent aerobic Gram-negative enteric bacilli, e.g. *Enterobacter* spp., *E. coli*, *Serratia marcescens*, *Klebsiella* and *Proteus* spp., *Ps. aeruginosa* and *Acetivobacter* spp. Gram-negative enteric bacilli are uncommon causes of community-acquired pneumonia except in elderly and debilitated patients often with comorbid conditions, whose flora has been modified by previous antibiotics, and in alcoholics [133]. Diagnostic uncertainty following the isolation of Gram-negative enteric bacilli in sputum is compounded by the frequency of oropharyngeal colonization by such organisms in these categories of patients.

### Non-severe infection

Most patients with community-acquired pneumonia in this group still respond to an aminopenicillin such as intravenous ampicillin 500mg four times daily or amoxicillin, which is appropriate in patients who are not severely ill. Failure to respond to this approach suggests the presence of  $\beta$ -lactamase producers or other resistant organisms, so that a  $\beta$ -lactamase-stable penicillin such as co-amoxiclav may be substituted. Alternatively,  $\beta$ -lactams such as cefuroxime (second-generation cephalosporin), cefotaxime or ceftriaxone (third-generation cephalosporins) may be given intravenously in this situation, since they are also resistant to the  $\beta$ -lactamases produced by *H. influenzae* and *Moraxella catarrhalis* while maintaining useful activity against the pneumococcus. The third-generation cephalosporins have less activity against the pneumococcus but excellent activity against Gram-negative enteric bacilli.

Where the patient is allergic to penicillin, amoxicillin is

omitted and a macrolide such as clarithromycin may be used alone initially in less ill patients. If the history of 'allergy' is not severe, then it is entirely reasonable to substitute a cephalosporin such as cefuroxime for the macrolide.

### Severe infection

Should the patient appear severely ill, the antibacterial spectrum may be broadened from the start by using the combination of an intravenous macrolide and an intravenous  $\beta$ -lactamase-stable antimicrobial such as cefotaxime or ceftriaxone. This retains adequate cover for the commonest organism (*Strep. pneumoniae*), which in the UK is almost invariably responsive to these  $\beta$ -lactams, as well as covering *H. influenzae*, *Moraxella catarrhalis* and *Staph. aureus* and the Gram-negative enteric bacilli, in addition to *Legionella pneumophila*, *Mycoplasma pneumoniae* or other macrolide-sensitive 'atypicals' such as *Chlamydia* spp. and *Coxiella burnetii*.

If staphylococcal infection is confirmed, then two antimicrobials active against this organism may be used as described above. Patients in this category who are known to be carriers of MRSA or who are admitted from a nursing home or other institution in which MRSA is known to be endemic may be treated with vancomycin 1g 12-hourly with the possible addition of rifampicin 600mg 12-hourly.

If the patient with severe infection has not improved within 24h, further diagnostic information may have become available that allows rational antibiotic adjustments. For example, urine testing by ELISA may indicate *Legionella* antigen, implying *L. pneumophila* type 1 infection, in which case intravenous rifampicin may be added to the macrolide.

As above, a past history of *serious* penicillin allergy in a case of severe pneumonia requires the omission of  $\beta$ -lactam antibiotic in general. Options include the use of clindamycin (Gram-positive cocci) with a macrolide such as clarithromycin (*Legionella* and other 'atypicals') or vancomycin (Gram-positive cocci) with ciprofloxacin (*Legionella* and other 'atypicals'). If as is usually the case, the history implies that allergy is not severe, consisting at worst of an uncomplicated rash rather than angio-oedema or anaphylaxis, then it is entirely reasonable to add a cephalosporin such as cefotaxime to the macrolide in order to provide some cover for methicillin-sensitive *Staph. aureus*.

The American Thoracic Society recommendation to cover Gram-negative enteric bacilli including *Ps. aeruginosa* from the start in patients with severe pneumonia is more relevant in elderly and debilitated patients with severe infection than it is in younger previously healthy patients, as the upper respiratory tracts of elderly patients are more likely to be colonized by these organisms, which

are also associated with underlying structural lung disease such as bronchiectasis or cystic fibrosis [60]. Gram-negative enteric bacilli are considered a rare cause of community-acquired pneumonia in the UK, so that although infection with *Ps. aeruginosa* has been associated with a high mortality [132], clinicians must use their own judgement in deciding whether to cover this organism. The options for covering Gram-negative enteric bacilli, including *Ps. aeruginosa*, while retaining activity against *Strep. pneumoniae*, *H. influenzae*, *Moraxella catarrhalis*, *Legionella* and the other 'atypicals' in this group of patients include a macrolide *plus* one of the following:

an antipseudomonal third-generation cephalosporin, e.g. ceftazidime;  
an antipseudomonal penicillin, e.g. azlocillin;  
ciprofloxacin;  
imipenem/cilastin or meropenem;  
aztreonam.

An aminoglycoside such as gentamicin may be added in order to augment antipseudomonal activity, at least initially. Aztreonam is unlikely to cause problems in a penicillin-allergic patient and ciprofloxacin is safe in the same situation.

As previously mentioned it should be noted that admission to an intensive care unit for more than a few days can be expected to result in overgrowth of the upper respiratory tract with Gram-negative enteric bacilli, especially if mechanical ventilation is used, with the potential for superadded Gram-negative enteric bacillary nosocomial pneumonia.

### Hospital-acquired (nosocomial) pneumonia

Hospitals can be regarded as areas of microbiological conflict in which the usual populations of oropharyngeal colonizers found in the community have a tendency to be driven out and to be replaced by other groups of organisms better suited to survival in these peculiarly hostile environments. This is important because it is known that small quantities of oropharyngeal secretions commonly find their way into the lower respiratory tract by microaspiration in entirely healthy individuals during sleep [38,134], so that in hospitalized patients these new colonials follow the same route and given the right circumstances may cause pneumonia.

Pneumonia occurring within 48 h of admission to hospital in an immunocompetent patient can usually be treated with the same antimicrobial approach as has been outlined above for community-acquired pneumonia, these patients being likely to have retained their community flora. Thereafter, assuming that infection was not being incubated at the time of admission, the pneumonia is regarded as being hospital-acquired with a potentially altered flora including Gram-negative enteric bacilli and *Staph. aureus*, so that a different approach is likely to be necessary [135].

### Concept of 'core organisms'

An individual physician's perception of the problem of hospital-acquired pneumonia may be easily skewed, as most of the published data refer to seriously ill patients in intensive care units rather than the mild to moderately ill ward-based cases often encountered in general hospital practice. Those patients who develop pneumonia earlier in their stay might still be expected to respond more in the manner of community-acquired pneumonia, the 'earlier' colonizers in these 'healthier' patients still tending to include *Strep. pneumoniae* and *H. influenzae*, followed in frequency by *Staph. aureus* [136], whereas those who develop pneumonia later are increasingly likely to be colonized by Gram-negative enteric bacilli, particularly if they have already received antibiotics [137–139]. The list of likely pathogens therefore becomes wider in nosocomial pneumonia [140]. The aerobic Gram-negative enteric bacilli include organisms such as *Enterobacter* spp., *E. coli*, *Serratia marcescens*, *Klebsiella* and *Proteus* spp., which together with *H. influenzae* and Gram positives such as methicillin-sensitive *Staph. aureus* and *Strep. pneumoniae* may be regarded as 'core organisms' to be anticipated and covered empirically in *all* patients with hospital-acquired pneumonia [139,141].

The chance of *Staph. aureus* being implicated in hospital-acquired pneumonia is increased if patients are admitted comatose, whereas Gram-negative enteric bacilli are more likely if patients become comatose *after* admission [142]. The reason for this is subject to speculation but it has been suggested that the first group have a tendency to aspirate earlier in their admission, when their oropharynx was more likely to be colonized by *Staph. aureus*, whereas the second group tend to aspirate later in their hospital stay, by which time oropharyngeal colonization with Gram-negative enteric bacilli would be more likely to have taken place [143]. The chance of *Staph. aureus* infection in hospital-acquired pneumonia is also increased by coexisting diabetes mellitus and renal failure [144].

### Further predictive situations

In addition to these core organisms, other pathogens in hospital-acquired pneumonia may be anticipated when certain predictive situations arise, in which case consideration can be given to further broadening the empirical antimicrobial spectrum to include these groups.

1 Highly resistant Gram-negative organisms such as *Ps. aeruginosa* and *Acinetobacter* spp. may be found especially in patients with severe illness who have required prolonged endotracheal intubation and mechanical ventilation in an intensive care environment, particularly if they have been treated previously with antibiotics or systemic corticosteroids [145,146]. *Ps. aeruginosa* is also a common

colonist in patients with underlying bronchiectasis or cystic fibrosis.

2 Anaerobic organisms should be covered if there has been a witnessed episode of overt aspiration of gastric contents, particularly if the patient has poor dentition, although it should be noted in these circumstances that anaerobes are not always responsible since:

- (a) the pneumonia could be chemical rather than infective; and
- (b) patients susceptible to hospital-acquired pneumonia have often had their gastric contents neutralized by  $H_2$  blockers or by gastric feeding, with the effect that their stomachs may be colonized by Gram-negative enteric bacilli and *Staph. aureus* so that these may be responsible for the pneumonia [147]. Anaerobes are also more likely to be causal pathogens if hospital-acquired pneumonia follows recent abdominal surgery.

3 It should be borne in mind that *Legionella* spp. may be important pathogens in some locations according to North American reports [148]. It is predisposed by concomitant high-dose systemic corticosteroid therapy [139].

#### Assessment of severity in hospital-acquired pneumonia

It has been recommended that the same criteria applied to community-acquired pneumonia may also be applied to cases of hospital-acquired pneumonia in order to assess its severity (see Table 13.4) and that this has a bearing on the choice of empirical antimicrobial therapy [139]. However, in contrast with community-acquired pneumonia the age of the patient is no longer a major determinant of antibiotic choice. There are therefore three important considerations that have a bearing on the choice of antimicrobial agents: (i) whether the patient's pneumonia is severe or not; (ii) the length of time that the patient has been in hospital prior to developing pneumonia; and (iii) whether predictive situations for certain organisms or groups of organisms exist.

#### Antibiotic regimens in non-severe hospital-acquired pneumonia

Patients with non-severe hospital-acquired pneumonia (mild to moderate) may be reasonably treated with a single agent that covers the 'core organisms' mentioned above, including the non-pseudomonal Gram-negative enteric bacilli, *H. influenzae*, *Strep. pneumoniae* and *Staph. aureus* (methicillin-sensitive). The options include:

- 1 a second-generation cephalosporin (such as cefuroxime);
- 2 a non-pseudomonal third-generation cephalosporin (such as cefotaxime);
- 3 a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor, e.g. amoxicillin/clavulanate (co-amoxiclav in the UK) or ampicillin/sulbactam (in the USA);

4 a fluoroquinolone (e.g. ciprofloxacin or ofloxacin) might be equally effective (except for *Strep. pneumoniae*) in penicillin-allergic patients;

5 clindamycin and aztreonam (effectiveness of aztreonam limited to Gram-negative enteric bacilli) may be used as alternative combination chemotherapy unlikely to cause problems in penicillin-allergic patients [139].

Initial treatment is usually intravenous, being stepped down to an oral agent with a similar spectrum (e.g. co-amoxiclav, ciprofloxacin) once a response has occurred.

In the predictive situation of overt aspiration, anaerobes may be covered by adding clindamycin or metronidazole or by using a  $\beta$ -lactam/ $\beta$ -lactamase (e.g. co-amoxiclav) alone. The more virulent and resistant Gram-negative organisms *Ps. aeruginosa* and *Acinetobacter* spp. may need to be targeted (as below) in certain predictive circumstances, such as in the presence of coexisting bronchiectasis or during a prolonged stay on an intensive care unit for whatever reason, even if the pneumonia is not severe. Treatment may need to include vancomycin in institutions where MRSA is endemic until this organism has been excluded.

#### Antibiotic regimens in severe hospital-acquired pneumonia

In patients with severe hospital-acquired pneumonia, intravenous antimicrobial treatment should usually be extended to cover *Ps. aeruginosa* and *Acinetobacter* spp. unless the pneumonia has occurred less than 5 days after admission, in which case infection with the 'core organisms' is more likely. The options include:

- 1 an antipseudomonal penicillin and an aminoglycoside, e.g. piperacillin and gentamicin;
- 2 an antipseudomonal third-generation cephalosporin and an aminoglycoside, e.g. ceftazidime and gentamicin;
- 3 the  $\beta$ -lactam carbapenem imipenem/cilastin or meropenem (also covers anaerobes) and an aminoglycoside;
- 4 an antipseudomonal penicillin/ $\beta$ -lactamase inhibitor combination and aminoglycoside, e.g. piperacillin/tazobactam (covers  $\beta$ -lactamase producers resistant to ureidopenicillins) and gentamicin.

Blood levels of the aminoglycoside should be monitored to both avoid renal toxicity and achieve the optimal bactericidal effect [149]. Ciprofloxacin may be used as an alternative to the aminoglycoside in any of the foregoing combinations and has less potential for toxicity [139]. It may be combined with gentamicin as an alternative treatment regimen in the penicillin-allergic patient. There is experimental evidence to support the use of more than one antibiotic active against Gram-negative bacilli, the combination of two such antibiotics acting synergistically [150]. Treatment may need to include vancomycin in institutions

where MRSA is endemic until this organism has been excluded.

### Supportive treatment in pneumonia

#### Respiratory support

Patients who are in obvious respiratory distress with tachypnoea are at increased risk of dying and need close monitoring, particularly if they are beginning to show evidence of exhaustion with drowsiness or confusion. Clearly such a patient is likely to be desaturated, with arterial hypoxaemia. The finding of a  $P_{aO_2}$  of less than 8 kPa (60 mmHg) when breathing room air indicates a serious situation, as does hypercarbia. Many patients are already receiving supplemental oxygen, in which case the ratio of arterial oxygen tension to fractional inspired oxygen concentration can be used, a  $P_{aO_2}/F_{IO_2}$  ratio equal to or less than 40 kPa (300 mmHg) having the same significance [60]. A  $P_{aO_2}$  of 6.7 kPa (50 mmHg) or less in the presence of a rising  $P_{CO_2}$  and acidosis are clear indications that mechanical ventilation may be necessary. Overcorrection of hypoxaemia should be avoided (see Chapter 55). Sometimes improvement in oxygenation can be achieved by postural change so that the 'good lung' is dependent [151,152]. Occasional patients may tolerate high-flow oxygen via a nasal continuous positive airway pressure system or nasal ventilation if they are sufficiently cooperative, not too tachypnoeic and untroubled by cough and sputum production.

#### Fluid and electrolyte replacement

Patients with severe pneumonia may become dehydrated so that their depleted intravascular volume requires par-enteral replacement. The situation may be further complicated if an intrapulmonary capillary leak develops, with resultant pulmonary oedema or adult respiratory distress syndrome (ARDS; see Chapter 27); such cases usually require mechanical ventilation with measurements of central venous or pulmonary capillary wedge pressure and meticulous attention to all aspects of fluid and electrolyte balance. Hypophosphataemia should be corrected if this arises [153].

#### Total parenteral nutrition

Total parenteral nutrition is best instituted early in severe cases of pneumonia in whom mechanical ventilation is likely to be prolonged. Intravenous feeding cannulae should be placed with great care in order to avoid their colonization by pathogenic organisms with consequent bacteraemia.

### Other considerations

#### Pleuritic pain

Pleuritic pain is usually easily relieved by simple non-sedative analgesics; care is taken to avoid narcotic analgesics with respiratory depressant properties in all but the mildest of cases.

#### Physiotherapy

Physiotherapy is of no benefit in an acutely ill patient who finds cooperation difficult and who may easily become exhausted, but it may assist expectoration of sputum in less ill patients and in those who are recovering [154].

#### Corticosteroids

Corticosteroids are not usually of convincing benefit either in patients with severe pneumonia or in those with systemic sepsis, although their use has caused debate [155,156]. They may be given in immunosuppressed patients with *Pneumocystis carinii* infection, when their use is thought to 'buy time' by suppressing the inflammatory response while the antimicrobial effect builds up (see Chapter 52).

#### Inotropic agents

Inotropic agents such as dopamine or dobutamine may be required when severe pneumonia is complicated by hypotension; indeed the requirement for vasopressors for more than 4 h was one of a number of features of severe pneumonia defined by the American Thoracic Society, as was a systolic blood pressure below 90 mmHg (12 kPa) or a diastolic blood pressure below 60 mmHg (8 kPa) [60].

## Specific microbiological types of pneumonia

### Pneumococcal pneumonia

#### Prevalence

Pneumococcal pneumonia is caused by *Strep. pneumoniae*, often referred to as the pneumococcus and classified in old literature as *Diplococcus pneumoniae* (Fig. 13.5). These Gram-positive diplococci are of extreme importance, being the most common cause of bacterial pneumonia. As the disease is not notifiable in either the UK or USA, data regarding its frequency in whole populations rely on estimation. In the USA an incidence of 1–5 cases per 1000 per year has been reported [158]. Other sources estimate a total of 150 000–570 000 cases per year in the USA, of which about 5% die [159]. Pneumococcal bacteraemia is also a

**Fig. 13.5** The ubiquitous Gram-positive pathogen, *Streptococcus pneumoniae* often appears in a diplococcal form ( $\times 14\,520$ ). (After Philips [157].)

serious problem in children worldwide, having been estimated to cause over 1 million deaths per year in those aged under 5 years [160].

The frequency with which evidence of pneumococcal infection is found in cases of pneumonia varies according to the methods used to detect infection and whether the patient has been treated with an antibiotic. Thus in the pre-antibiotic era, *Strep. pneumoniae* was found to be responsible for 96% of over 3000 cases of lobar pneumonia reported in one survey and in another to account for almost 80% of 350 cases of pneumonia [161,162]. In more recent studies the failure to isolate the pneumococcus (or indeed any organism) has become commonplace, leading to microbiological complacency and inertia on the part of clinicians that has been condoned in the literature [163]. Thus a paper published in 1974 found no organism in 37% of 203 cases of lobar pneumonia and isolated *Strep. pneumoniae* in only 8% [164]. A district general hospital survey from Bristol in 1981 found evidence of a specific infective organism in only 46% of cases and *Strep. pneumoniae* in only 11%, previous antibiotics having been given 'blind' in 75% of cases [165]. The view that this apparent reduction in prevalence is in part due to prior antibiotic suppression

of growth is supported by a serological study using CIE, which found evidence of pneumococcal infection in 72% of cases of pneumonia against a culture isolation rate of only 9% [166]. Further support for this view was provided by a painstaking hospital study from Nottingham that claimed to identify the causative organism in 97% of 127 patients, pneumococcal infection accounting for 76% of cases [167]. A multicentre British Thoracic Society study has also confirmed that *Strep. pneumoniae* is the most frequent causative organism in cases of pneumonia admitted to hospital from the community [35]; a similar experience has been reported from some North American centres [168].

#### *Pathological anatomy and pathogenesis*

A micrococcus was described postmortem by Friedländer in cases of pneumonia over a century ago and was thought to be a probable aetiological factor. The pathological anatomy of lobar pneumonia has also been admirably described since Lænnec's day [29]. Three stages were then recognized. The first stage is one of inflammatory congestion, in which the affected part of the lung is coloured dark

red due to hyperaemia; the air in it is diminished but not absent, affected alveoli and bronchi beginning to fill with a fluid and haemorrhagic exudation. In the second stage (red hepatization), the exudate coagulates so that the lung assumes the consistency of liver (Fig. 13.6). In the third stage, the red appearance of the cut surface of lung changes to become yellowish-grey (grey hepatization), the numbers of red cells in the exudate diminishing and being replaced by neutrophils (Fig. 13.7). When resolution takes place, the exudate liquefies and is coughed up or otherwise absorbed, the neutrophils phagocytosing the pneumococci and monocytes clearing up the fibrinous debris so that the lung is restored to its former state. A case of lobar pneumonia need not go through all three classical stages and different stages of the process may occur at the same time in an individual case. The entire cycle is relatively short, running its course in 7–10 days. If resolution is incomplete, the fibrinous exudate organizes so that aveoli become filled with a mass of fibroblasts that may result in permanent scarring.

Classically, pneumococcal pneumonia produces diffuse involvement of most of a lobe and more than one lobe may be involved in 10–25% of cases but spread of consolidation throughout an entire lung is unusual, occurring in less than 1% of patients [169]. Segmental or subsegmental involvement may also occur, these types being more common in children, the elderly and in those with underlying chronic pulmonary disease.

There are at least 84 distinct serotypes of pneumococci, their identification being based on antigenic differences in their polysaccharide capsules. The variable pathogenicity of these individual pneumococcal subtypes is incompletely understood but the chemical composition of the capsule is important in determining the virulence of the organisms. This is partly related to the degree of inhibition

of phagocytosis afforded by the type-specific capsular polysaccharides, which do not themselves appear to stimulate an inflammatory response; however, the sub-capsular cell wall is able to stimulate considerable inflammation, with the alveolar exudation of fluid in which the organisms multiply and are spread throughout a lobe [170–172]. *Strep. pneumoniae* is an extracellular pathogen and in order for it to be removed it has to be phagocytosed. The whole process is complex, involving opsonization with serotype-specific capsular antibodies, complement and C-reactive protein with the participation of alveolar macrophages and neutrophils [173]. The molecular events that transform a tranquil pharyngeal colonist into the seemingly aggressive pathogen that causes rapidly progressing pneumococcal pneumonia are incompletely understood but it is known that pneumolysin, and other components, including cell-wall material are released as neutrophils destroy the invading organisms and that these act as toxins, leading paradoxically to increased inflammation and cellular damage in the lung [172].

### Epidemiology

Pneumococcal pneumonia is slightly more common in males than females throughout life, for reasons that are unclear. It also becomes more common with increasing age, so that an attack rate of about 46 cases per 1000 over the age of 40 years has been noted [44] compared to 1–5 per 1000 per year for the population overall [174]. It has been estimated that it is responsible for 30–50% of all cases of community-acquired pneumonia in the UK [175]. Pneumococcal bacteraemia shows a bimodal age distribution, 50% occurring in patients over the age of 65 years, with another large peak in infants under the age of 1 year,

**Fig. 13.6** Necropsy specimen showing early stage lobar pneumonia, with alveoli containing a fibrinous coagulum and relatively few leucocytes (haematoxylin & eosin  $\times 12$ ).

**Fig. 13.7** (a) Lobar pneumonia at a later stage than Fig. 13.6 showing normal alveolar architecture and dense confluent polymorphonuclear intra-alveolar infiltrate (haematoxylin & eosin  $\times 112$ ). in whom pneumococcal meningitis is mainly reported [176].

Pneumococcal pneumonia occurs more frequently in the winter months in temperate climates and at the end of the dry season in the tropics [177]. Each year the number of reports of bacteraemic pneumococcal infection in England and Wales increase sharply in the first quarter and are at their lowest in the third quarter [178]. It is possible that an individual patient's defences against the pathogenicity of *Strep. pneumoniae* may be compromised by a preceding viral upper respiratory tract infection [179]. This would accord with the observation that coryzal symptoms frequently precede the onset of pneumococcal pneumonia and also with the observed increased seasonal incidence of common cold virus infections in winter [180]. Furthermore, pneumococcal pneumonia is the most common serious bacterial complication of influenza and

measles, both of which show an increased winter prevalence; indeed the advent of an influenza epidemic may be heralded by a rise in the number of cases of pneumonia in the community [21]. In order to induce pneumococcal pneumonia experimentally in monkeys, it is necessary to inoculate the pneumococcus into the trachea rather than the nasopharynx [181]. Similarly in humans, infection in the nasopharynx is commonplace, this being the organism's usual ecological niche, up to 70% of the population acting as asymptomatic carriers of *Strep. pneumoniae* at some time or other. In view of this it is remarkable that pneumococcal pneumonia does not occur more frequently. It is thought that pneumonia is unlikely to occur in the absence of microaspiration of infected mucus from the nasopharynx in a subject whose defences are compromised by some other factor such as viral infection.

At least 84 distinct types of *Strep. pneumoniae* have been

identified according to the antigenicity of their polysaccharide capsules (see p. 380) [172]. Although all these types may be carried asymptotically, some have greater pathogenicity than others and it is microaspiration of the more virulent strains that causes trouble for humans. The majority of the pneumococcal types carried by the normal population are not commonly associated with pneumonia, although they may rarely cause it, and are sometimes referred to as 'carrier types'. About two dozen of the more pathogenic or 'infective types' of pneumococcus are responsible for 80% of cases of pneumococcal pneumonia, type 3 being particularly virulent [22,182,183]. Carrier rates for the various antigenic types have been noted to be higher in closed communities such as schools and barracks and high attack rates have been recorded in encampments of military personnel and South African gold miners [184,185].

Epidemics have been unusual since the introduction of antibiotics. When they do occur, several serotypes are usually implicated in a population with a high carrier rate that is attacked by predisposing viral infection [184,186]. During such epidemics the asymptomatic nasopharyngeal pneumococcal carrier rate goes up and carriers may develop pneumonia themselves or transmit the organism by droplet spread to others, who then become similarly susceptible. One such epidemic was recently reported in an overcrowded and poorly ventilated prison, caused on this occasion by a single serotype (12F), with a carriage rate of 7% within the prison population and with no evidence of any predisposing respiratory viral infection [187]. Cell blocks with the worst combination of crowding and poor ventilation had the highest rates of disease. Another such outbreak was reported in relation to two shelters for homeless men [188], and a third outbreak caused by a single multidrug-resistant strain (23F) was reported in unvaccinated nursing home residents [189]. In general, asymptomatic carriage of the pneumococcus decreases as age increases, except in relatively closed communities where rates may be disproportionately high. Although asymptomatic pneumococcal carriers are firmly implicated in the spread of infection, cases of direct patient-to-patient spread of disease are recorded [190–192].

### *Predisposing factors*

Pneumococci that enter the bloodstream are dealt with by the reticuloendothelial system. The spleen clears bacteria from the blood and also acts as a store for B lymphocytes that respond to capsular polysaccharide antigens by producing the appropriate antibodies. Subjects who have had a splenectomy, either for the treatment of abdominal trauma or for haematological disorders such as thrombocytopenia or lymphoma staging, have a small but well-documented lifelong increase in susceptibility to

pneumococcal infection that is probably greatest in the first two postoperative years [193]. Such patients (over the age of 2 years) should be offered pneumococcal vaccination (see p. 381) 2 weeks before elective splenectomy or before discharge from hospital if the spleen has been removed as an emergency [195]. Patients with functional asplenia due to various causes are also more susceptible. These include homozygous sickle cell disease (in which the risk of pneumococcal sepsis is increased several hundred fold), thalassaemia and adult coeliac disease [195–197]. Pneumococcal bacteraemia in asplenic patients is often overwhelming, with no obvious focus of infection, and may be associated with disseminated intravascular coagulation (DIC) and multiple organ failure [198–200]. Susceptible asplenic patients should be educated about the risks they face and encouraged to wear a medical warning (e.g. 'Medic Alert') bracelet. They should also be immunized against *H. influenzae* type b and *Neisseria meningitidis*. Local audits of such measures have shown them to be effective in achieving uptake of vaccination [201]. There are a number of other groups who are more susceptible to pneumococcal pneumonia or in whom the mortality from pneumococcal pneumonia is higher, including those patients, many of whom are elderly, with chronic lung disease, congestive heart failure, chronic renal disease (including nephrotic syndrome), chronic liver disease (including cirrhosis), diabetes mellitus and inherited or acquired immunodeficiency states including hypogammaglobulinaemia, IgG subset and complement deficiencies, neutropenia, leukaemia, lymphoma and amyloidosis [173].

Immunosuppressed HIV-positive patients are at increased risk of developing bacterial pneumonia and *Strep. pneumoniae* is the most commonly isolated pathogen in such cases, having been reported to precede the onset of AIDS in approximately 60–80% of this population [202]. The clinical presentation in such cases is generally indistinguishable from that occurring in normal hosts but bacteraemia is more common and the mortality somewhat higher in HIV-positive cases [203]. HIV testing should be considered in patients who are younger than 40 years of age and who present with pneumococcal pneumonia, as this may be the first manifestation of their compromised immunity [204,205].

### *Clinical features*

Classical lobar pneumonia in a previously healthy subject results in an acute febrile illness. The onset of the illness is frequently preceded by mild coryza or other upper respiratory tract symptoms of presumed viral origin. Symptoms may begin abruptly with a high fever often heralded by a rigor or 'shaking chill' (Fig. 13.8). Before the availability of antibiotics a patient would remain febrile with a continuous fever, typically 38.5–39.5°C, for between 5 and 10

Fig. 13.8 Temperature, pulse and respiration chart of patient with pneumococcal pneumonia showing typical response to intravenous penicillin.

days. If recovery occurred it was characteristically abrupt, with a sudden fall in temperature, the so-called 'crisis'. Pleuritic pain over the affected lobe is common and when present makes coughing painful. The cough may be dry initially but is later productive of sputum. This is classically described as being a rusty-brown colour as a result of the release of red blood cells into the alveolar exudate in the phase of red hepatization. Nowadays this is a less common finding, presumably because of the modifying effect of antibiotics on the pathological process, and the sputum is usually a non-specific yellow or greenish colour, sometimes containing small flecks of blood.

On physical examination the patient may be sweating, flushed and ill-looking. Cyanosis is uncommon in a previously healthy patient and when present indicates extensive pneumonia with a sizable shunt effect. A fever and concomitant tachycardia are present. Tachypnoea is usually present and breathing may be limited in depth by pleuritic pain. An impaired percussion note may be elicited over the affected lobe. The breath sounds are usually bronchial in quality over the same area; when this is the case the other signs of consolidation, namely

increased vocal fremitus and resonance, aegophony and whispering pectoriloquy, are also elicitable. Localized crackles may be heard. Herpes labialis (herpes simplex infection of the lips) is a common finding within a few days of the onset of infection.

Although the foregoing clinical features are well recognized in relation to lobar pneumonia, in a microbiological sense they are entirely non-specific and it is impossible to conclude with certainty that the infective organism is *Strep. pneumoniae* without supporting evidence from the laboratory. Furthermore, the classical presentation in modern-day practice is often modified by (i) the early use of antibiotic therapy, (ii) the presence of pre-existing lower respiratory tract disease such as chronic bronchitis, emphysema and bronchiectasis, and (iii) the age of the patient. Thus although fever may be present in the elderly, this is by no means always the case, even in the presence of bacteraemia [206,207]. Rigors, cough and pleuritic pain may also be absent [208]. Loss of mental clarity, somnolence or frank confusion are also found commonly in elderly patients with pneumonia of any type [209], and may be a manifestation of the pneumonia itself or of deterioration in a coexisting illness such as renal insufficiency or congestive heart failure [4,44]. As with the elderly, so symptoms in young children may be non-specific and misleading. Fever and delirium are common. Respirations may be rapid and grunting. Meningism is sometimes present and abdominal pain may occur in lower lobe pneumonia. The usual auscultatory findings of consolidation may be absent or difficult to detect, making a chest radiograph essential for diagnosis.

## Investigations

### Haematology and biochemistry

The blood count usually shows a polymorphonuclear leucocytosis. In the elderly and where the infection is overwhelming, the white cell count may be normal or there may be leucopenia [206]. A marked leucocytosis (exceeding  $30 \times 10^9/L$ ) or leucopenia ( $<4 \times 10^9/L$ ) have also been found to be associated with a poor prognosis [4]. Severe infection is occasionally accompanied by DIC and the syndrome of inappropriate ADH secretion may occur. The erythrocyte sedimentation rate is usually raised and it falls as clinical improvement occurs. If it remains raised, then another disease or other complicating factors should be considered.

### Chest radiography

The chest radiograph classically shows homogeneous hazy shadowing occupying the anatomical distribution of a lobe (Fig. 13.9). Shadowing need not involve the whole lobe, but if most of it is included then it is conventionally

(a)

(b)

**Fig. 13.9** (a) Right upper lobe pneumococcal pneumonia in a child following influenza showing classical lobar consolidation. The radiograph cleared within 2 weeks of starting penicillin. (b) Right lower lobe consolidation of more patchy distribution in a patient with emphysema. Pneumococcus was cultured from blood.

classified as lobar. Any part of the lung may be involved, although the lower lobes are most commonly affected. The density of the shadowing varies according to the intensity of the pneumonic exudation. Although pneumonic shadowing in *Strep. pneumoniae* infection is more commonly homogeneous than patchy [210], this feature does not reliably serve to distinguish it from other pneumonias such as *Mycoplasma*, *Legionella* and psittacosis. *Klebsiella*

pneumonia is also classically lobar in distribution. In patients admitted to hospital with pneumonia, cases with radiographic evidence of lobar consolidation are less common than those in whom consolidation is radiographically confined to one or more segments or subsegments, sometimes in different lobes [211]. Radiographic clearing usually occurs over 3–6 weeks and is nearly always complete. This radiographic delay contrasts with the generally

rapid clinical response to treatment with antibiotics, which is measured within hours or days.

#### *Blood gases*

Arterial blood gas analysis is an important gauge of severity (see Table 13.4, p. 360) and may show hypoxia and hypocarbia, with a respiratory alkalosis due to shunting of blood through consolidated lung [212]. Hypercarbia may occur if there is coexisting chronic bronchitis and emphysema or in severe cases if the patient is becoming exhausted.

#### *Microbiological tests*

Blood culture is normally carried out routinely and is positive in about 30% of cases. Sputum examination is best carried out expeditiously but antibiotics should not be delayed if a specimen is not readily obtainable. Gram staining of expectorated sputum in pneumococcal pneumonia is reported to have a sensitivity and specificity of 62 and 85% respectively [213]. The characteristic sputum finding in pneumococcal pneumonia is the presence of Gram-positive diplococci, some of which may be contained within polymorphs. If standard pneumococcal antisera are available (obtained by immunizing rabbits with pneumococci), then *Strep. pneumoniae* can be rapidly identified and typed using the Quellung (Neufeld's capsular precipitin) reaction, in which specific antibodies in the standard antisera react with capsular antigens on the surface of the pneumococci being tested. The Quellung reaction can be applied to sputum or other clinical specimens.

Since it is not uncommon for patients admitted to hospital with pneumonia to have received an antibiotic beforehand, positive cultures in these subjects are unusual. A positive diagnosis may be made from sputum microscopy and culture in about 50% of patients with pneumococcal pneumonia, although this figure may be reduced by half in the elderly [66,206]. It must be remembered that expectorated sputum may contain contaminants that colonize the nasopharynx commensally and these may include *Strep. pneumoniae*, staphylococci, *H. influenzae* and *Moraxella catarrhalis* [214].

Pneumococcal (polysaccharide capsular) antigen detection is carried out routinely in some centres usually using latex agglutination or, less commonly, CIE. Pneumococcal antigen detection has been found to be less sensitive when applied to blood (<25%) than urine (about 40%), being most sensitive when used on mucopurulent sputum (about 80%) [94,95]. This compares with a sensitivity of about 50% when the Gram stain is applied to sputum for the same purpose. The investigation can also be applied to pleural fluid and to lung secretions that have been obtained invasively using percutaneous ultra-thin needle aspiration and bronchoalveolar lavage (see p. 362), so that

the sensitivity of these tests may be increased [96–98]. The specificity of sputum pneumococcal antigen for detecting cases of pneumococcal pneumonia is reduced to about 70% because *Strep. pneumoniae* is often isolated from the sputum of patients with chronic bronchitis who do not have pneumonia. A positive sputum pneumococcal antigen test may also not differentiate between oropharyngeal colonization and pulmonary infection; furthermore some capsular antigens are difficult to detect by these methods. Pneumococcal antigen testing has been useful in research to establish the relative frequencies with which different organisms are found in population studies of pneumonia, since it has the particular advantage that its sensitivity is unaffected by prior antibiotic treatment, unlike the various culture techniques. Despite this, it has not established itself as a routine test in most general hospital laboratories. Although the routine use of pneumococcal antigen testing is expensive and requires technical expertise, it does have the advantage of providing rapid information and might be usefully applied in the sicker patient in whom routine cultures are likely to have been suppressed by previous treatment with a broad-spectrum antibiotic. Pneumococcal antigen may be detected in the serum or urine of 50% of patients with pneumococcal pneumonia who are non-bacteraemic in terms of negative blood cultures. The antigen remains detectable for 7–14 days after bacteraemic pneumococcal pneumonia.

Pleural fluid, if present in sufficient quantity, should be aspirated and submitted for Gram stain and culture and the usual chemistry as referred to above. If pus is not found and the patient is on an antibiotic, the fluid is frequently sterile but may still be submitted for pneumococcal antigen testing if this is available.

#### *Treatment*

In many parts of the world penicillin-insensitive pneumococci are still uncommon, although in general protocols for treating *Strep. pneumoniae* infections do have to take into account the local prevalence of penicillin resistance, particularly in the case of pneumococcal meningitis. Benzylpenicillin (penicillin G) is still the antibiotic of choice for bacteriologically confirmed pneumococcal pneumonia, having greater activity against this organism (MIC usually <0.06 mg/L) than amoxicillin or ampicillin. Despite this, the aminopenicillins ampicillin or amoxicillin, with or without a  $\beta$ -lactamase inhibitor, are often prescribed to good effect by clinicians concerned about using a narrow-spectrum penicillin without positive identification of the organism, particularly in older patients with comorbidity. The first 2 days of treatment in hospital is often given parenterally, although the need for this in all cases is debatable. A benzylpenicillin dose of 1.2 g (2 megaunits) i.v. 6-hourly is usual, although the intramuscular route is feasible and higher doses may be

used in severe infection. Parenteral penicillin may also be continued for longer than 2 days according to the clinical response, although this is not often necessary with uncomplicated pneumonia. Parenteral therapy may be followed by oral amoxicillin at a dose of 500 mg orally 8-hourly, or if ampicillin is chosen 500 mg orally 6-hourly. Phenoxymethylpenicillin (penicillin V) 500 mg 6-hourly for 7 days can be used as an alternative to an oral aminopenicillin but is less well absorbed. When a patient is allergic to penicillin, a macrolide such as erythromycin may be used instead, 0.5–1 g being given intravenously every 6 h for 48 h (commonly causing phlebitis and therefore not given in bolus form) to be followed by 250–500 mg orally 6-hourly for 7 days. It should be borne in mind that the Central Public Health Laboratory in England reported pneumococcal resistance to erythromycin in 8.6% of strains that it tested [115]. This resistance extends to those newer macrolides such as clarithromycin that may be used in place of erythromycin. These cause less nausea and need less frequent dosing but are more costly. Resistance rates to macrolides of 6–19% are reported in the USA, these rates being significantly higher for penicillin-resistant strains of pneumococci [121]. Cefuroxime 1.5 g i.v. 8-hourly may be used as an alternative to parenteral erythromycin in patients who report rashes in response to penicillin, although cross-allergenicity between penicillins and cephalosporins may occur in about 10% of patients. Alternatives that might be preferred in the presence of pulmonary comorbidity are cefotaxime 1 g i.v. 8-hourly or ceftriaxone 2 g i.v. once daily. Some cephalosporins (e.g. ceftazidime and cefoxitin) are significantly less active against the pneumococcus than penicillin and are best avoided where this is the known pathogen. Newer fluoroquinolones such as sparflaxacin, which have much greater efficacy against the pneumococcus than ciprofloxacin and ofloxacin, offer an alternative but further published data on their clinical efficacy in this situation are awaited.

Where much higher levels of penicillin are required for adequate penetration, as for example in rare cases of complicating meningitis or endocarditis or in septic arthritis or empyema, then much higher doses of benzylpenicillin of up to 24 g (40 megaunits) i.v. daily in divided 4–6-hourly doses have been given.

Penicillin-resistant forms of *Strep. pneumoniae* (see below) were well described in the 1970s [215]. Although at that time rare in Europe and North America, penicillin resistance has now become a global problem, being no longer confined to certain parts of the world such as South Africa and New Guinea where epidemics of pneumococcal pneumonia led to the widespread use of prophylactic penicillin in certain locations [215,216]. Because of potential or real problems with penicillin insensitivity, a careful watch has to be kept for possible clinical treatment failures and closer attention has to be paid to patterns of antibiotic

sensitivity when pneumococci are isolated so that treatment may be changed if necessary. Benzylpenicillin is still usually effective for pneumococcal pneumonia even in areas where the prevalence of penicillin-resistant organisms is high and can still overcome organisms with an intermediate or even high level of resistance. However, treatment failures may occur in pneumococcal meningitis because penicillin may not achieve adequate cerebrospinal fluid (CSF) levels to deal with insensitive organisms and the best way of dealing with this situation is still a matter of debate. One suggested approach is to use a combination of an extended-spectrum third-generation cephalosporin such as cefotaxime or ceftriaxone and vancomycin in children or adults with suspected pneumococcal meningitis in areas where penicillin resistance is known to be a significant problem, treatment being continued with a single drug when the results of sensitivities are available [217,218]. Vancomycin is currently regarded as the single most effective antibiotic for treating meningitis caused by penicillin-resistant pneumococci.

The temperature in patients with pneumococcal pneumonia usually starts to fall within 24–48 h of commencement of an appropriate antibiotic (Fig. 13.8). If it does not, then the possibility of another infecting organism, a resistant pneumococcus, allergy to the antibiotic, a collection of pus or a diagnosis other than pneumonia should be considered. Response to treatment in meningitis is usually slower but improvement should be detected within 5 days, treatment being continued for 10–14 days. Complicating endocarditis, septic arthritis or pleural empyema may well require treatment for 6 weeks.

General supportive therapy is discussed above, and includes the provision of oxygen at sufficient concentration to correct hypoxaemia. The usual constraints to oxygen therapy apply when the patient has coexisting chronic obstructive pulmonary disease, with possible respiratory centre dependency on hypoxic drive (see Chapter 23). Pleuritic pain is treated with appropriate analgesia. Narcotic analgesics are not usually required but may be given in the absence of serious hypoxaemia, alveolar hypoventilation or obstructive pulmonary disease.

## Prevention

### Vaccination

Pneumococcal pneumonia remains the most common form of community-acquired pneumonia and it causes large numbers of deaths. A significant proportion of these deaths occur in association with bacteraemia despite early treatment with appropriate antibiotics and, peculiarly, the mortality has remained fairly constant over the last four decades at around 25% in such bacteraemic cases [217,219]. For these reasons attention has been focused on prevention by means of vaccination [158]. Efforts in this

direction are not new and the first trial of such a vaccine was carried out during the Second World War [220]. Interest rapidly faded, however, following the advent of penicillin in 1944 and did not reawaken until the 1960s, the vaccine only becoming available in the UK in 1979.

Immunization against *Strep. pneumoniae* is desirable in those groups of the population most likely to develop the infection and in those who, if they do develop it, have a greater risk of dying as a result. Pneumococcal infection is more common in the elderly [44] and in patients who have had a splenectomy or who have splenic dysfunction, such as occurs in sickle cell anaemia as a consequence of multiple small infarcts and in coeliac disease [221–223]. Groups in whom the mortality from pneumococcal pneumonia is higher include the elderly and those with chronic pulmonary or cardiac disease, chronic renal insufficiency, chronic liver disease or alcoholism and diabetes mellitus [224].

The vaccines at present commercially available in the UK and USA are complex polyvalent preparations currently based on the capsular polysaccharide antigens of 23 pneumococcal types that are responsible for over 80% of episodes of bacteraemic pneumococcal infection in the USA, the distribution of serotypes in the UK being broadly similar [225,226]. The vaccines (Pneumovax II and Pnu-Imune) may be given subcutaneously or intramuscularly. Local tenderness is a common side-effect but fever occurs in less than 5% of subjects [227].

Although it is agreed that pneumococcal pneumonia is well worth preventing, there is no shortage of controversy about the ability of the vaccine to provide adequate immunity in those patients at special risk. It does not apparently influence nasopharyngeal carriage rate in normal subjects but has been shown to be effective in preventing pneumonia in controlled trials involving immunocompetent young men and in relatively isolated or crowded populations, such as South African gold miners, highland town dwellers in Papua New Guinea and military recruits, all of whom were susceptible to epidemic pneumococcal pneumonia [220,228–231]. Unfortunately the evidence of benefit in elderly populations and those with chronic disease who are at particular risk from sporadic disease has been more conflicting. It has been estimated that a large, prospective, randomized, placebo-controlled trial involving 100 000 subjects would be required to remove doubts about whether vaccination is effective in these subjects and a project of such a size would not receive funding or even ethical approval, in view of the fact that government health agencies already recommend widespread use of the vaccine [232]. In the mean time the evidence is conflicting. One well-designed, placebo-controlled, randomised, double-blind study of 2295 high-risk patients aged over 55 years was unable to demonstrate the efficacy of pneumococcal vaccine in preventing pneumonia or bronchitis [233]. Another study of only 43 patients with

chronic bronchitis and emphysema showed that pneumococcal vaccine did not diminish the frequency of isolation of *Strep. pneumoniae* from the sputum and also found that the levels of antibody to the various vaccine strains of pneumococcus were high before vaccination [234]. These findings raised doubts about the recommendations of the US Centers for Disease Control, which have been based on retrospective analyses and have been taken to indicate that the vaccine is useful in preventing bacteraemic complications in elderly patients, a hypothesis supported by an earlier case-control study [159,235,236]. It has been suggested that elderly patients at risk from pneumococcal bacteraemia should be vaccinated before hospital discharge, since a high proportion of patients with pneumococcal bacteraemia were found to have been in hospital within the preceeding 5 years [237–239]. A large and more recent case-control study claimed to show an overall efficacy for the vaccine of 56%, patients with severe pneumococcal infection being less likely to have been vaccinated than a control group [240]. In immunocompetent persons the protective efficacy was 61% but it varied a good deal with age, from 93% in those aged less than 55 years to 46% for those aged 85 years or more. It is possible that relative immune incompetence may be a reason for the vaccine's diminished efficacy in some elderly or chronically sick patients. This has led to the suggestion by some that any vaccination programme would be more likely to be successful were the vaccine to be administered at an earlier age [241]. An uncontrolled indirect cohort study took 2837 patients in whom the pneumococcus had been isolated from blood or CSF and then investigated their vaccination history, finding that those who had been vaccinated were less likely to have been infected by a serotype contained in that particular vaccine than by a serotype not in the vaccine. Using this method, these workers claimed to demonstrate an overall vaccination efficacy of 57% and an efficacy of 75% in those aged over 65 years [242]. The vaccine's efficacy in non-bacteraemic pneumonia is less easy to evaluate because of the lack of non-invasive methods for reliably diagnosing this type of illness. A single-blind trial of 2837 subjects over the age of 60 years, who were randomized so that half received both 14-valent pneumococcal vaccine and influenza vaccine and half influenza vaccine alone, found no significant difference in the overall frequency of pneumococcal pneumonia over 3 years, although there was a statistically significant preventive efficacy of 59% in a subgroup with chronic disease risk factors [243].

The efficacy of pneumococcal vaccination was found to be only 21% in patients who were immunocompromised for reasons other than HIV infection [240,244]. This group includes patients with acute leukaemia, chronic lymphocytic leukaemia, Hodgkin's disease and multiple myeloma. This has led to doubts about whether it confers significant protection in patients who are serologically

HIV positive, although both North American and British agencies recommend its use in this patient group [245,246]. The concern is that at least some HIV-positive patients may not be able to mount an effective antibody response to the vaccine [247]. This may well be the case as HIV infection progresses so that a pragmatic but unproven policy is to vaccinate seropositive HIV patients as early as possible, while the CD4<sup>+</sup> (T-helper) lymphocyte count is greater than  $0.2 \times 10^9/L$ , or even to vaccinate HIV-negative subjects who belong to groups that are at high risk of subsequently becoming positive [248]. In HIV-positive patients about to start antiretroviral therapy, it has been argued that pneumococcal vaccination should be delayed for a few weeks in the hope that their ability to mount an immune response improves [249].

It can be stated with conviction that pneumococcal vaccination is safe and, whether it is applied to the elderly and those with chronic disease or not, it can be used effectively in younger immunocompetent subjects who may be at risk in geographically localized outbreaks or in outbreaks caused by resistant organisms. In addition, vaccination can be strongly recommended in subjects at risk (see Table 13.5, p. 385), such as those about to undergo elective splenectomy, those who have undergone emergency splenectomy and those with splenic dysfunction as occurs in sickle cell anaemia and coeliac disease. Children under the age of 2 years (who cannot mount an adequate antibody response to unconjugated polysaccharides) should not be vaccinated but those at risk may be protected by twice-daily oral penicillin.

Antibody levels following immunization may wane to low levels after about 5 years; as the antibody response tends to be weaker and of shorter duration in asplenic patients than in those with normal immunity, it is suggested that such patients should be revaccinated after 5–10 years [193,241]. Protection may last for an even shorter time in some patients known to have a particularly rapid antibody decline, such as those with the nephrotic syndrome, renal failure and also organ transplant recipients, prompting some to suggest that such patients should have their antipneumococcal antibody levels monitored annually following immunization so that a more informed decision might be made about the most appropriate time to revaccinate [173]. However, it remains somewhat unclear as to what antibody level is protective and most immunology laboratories only measure a selected few of the 23 serotypes in use. Revaccination within 5 years in subjects who still have significant antibody levels may give rise to an unpleasant local reaction. The vaccine should not be given during pregnancy or to those who are acutely ill.

Research into the efficacy of new protein-conjugate pneumococcal vaccines is underway in the hope that these will offer better protection, as well as being protective in infants under the age of 2 years. The pneumococcal poly-

saccharide capsules in these conjugated vaccines are attached to a protein carrier in a similar manner to that used in the successful conjugated *H. influenzae* type b vaccine, in order to attain a higher degree of immunogenicity with a better concentration of circulating capsular antibodies. One current drawback with these vaccines is that they are pentavalent, it being possible to conjugate only seven capsular polysaccharides to the protein carrier.

Asplenic patients should also be vaccinated against *H. influenzae* type b and *Neisseria meningitidis* groups A and C. Although two-thirds of isolates in the UK are group B and therefore not covered by the existing meningococcal vaccines, a B vaccine is under development. These patients are also at increased risk of malaria.

### *Antibiotic prophylaxis*

Antibiotic prophylaxis is considered essential in patients following splenectomy, although the optimal duration of therapy is undetermined and the subject of conjecture [194]. The first 2 years after splenectomy is considered to be the time of greatest risk, although a lesser risk of serious pneumococcal infection is lifelong. The Department of Health recommends that all children should receive penicillin prophylaxis after splenectomy and it would seem reasonable to continue this up to the age of 16 years or as long as the child remains in the care of their parents, after which problems with compliance often increase [193]. A reasonable policy in adults is to discuss the risks and to treat with prophylactic penicillin for 2 years and thereafter, in patients judged to be compliant, to ensure that a small supply of antibiotic is available so that self-treatment can start promptly at the first sign of a febrile illness, after which medical advice can be taken [250–253]. Some authorities have recommended lifelong antibiotic prophylaxis but the drawbacks of this include the likelihood of poor compliance as well as the potential for encouraging the emergence of antibiotic-resistant bacterial strains [254]. Prophylactic penicillin has also been shown to prevent pneumococcal infection in functionally asplenic Jamaican children with homozygous sickle cell anaemia and should be given to such children from the age of 3 months at least until the age of 2 years, when they should be vaccinated (see above) [255].

Usual prophylactic dosages are phenoxymethylpenicillin 500 mg for adults, 250 mg for children aged 6–12 years and 125 mg for children aged less than 6 years, all taken twice daily. Others have recommended amoxicillin 500 mg daily for adults and 250 mg daily for children in order to extend cover to *H. influenzae* as well [253]. Penicillin-allergic subjects may take erythromycin 250 mg twice daily for adults and children over 2 years of age, the dose being reduced to 125 mg twice daily in younger infants.

### Problems with penicillin resistance

Penicillin-resistant pneumococci were unheard of before 1967 when the first isolates were cultured in patients living in remote parts of Papua New Guinea. The problem was subsequently reported in Australia and South Africa and by the 1990s had become global. Over 40% of isolates in Spain, Iceland and some eastern European countries such as Hungary show reduced susceptibility to penicillin. High prevalence rates have also been reported in parts of South America and South Africa and recent data have shown a rate of 25% in the USA, over 40% of isolates from white children under the age of 6 years in Atlanta being resistant to penicillin [256]. The prevalence in the UK is 5–10% and that in Australia reportedly about 7%. It is not uncommon for quite wide geographical variations in the prevalence of resistant pneumococci to be reported within a single country and thus it is important for clinicians to have some knowledge of the microbiological resistance patterns in their own locality.

Resistance is likely to have arisen largely because of the heavy and indiscriminate use of penicillin, sometimes as prophylaxis in crowded communities prone to epidemics of pneumococcal infection; clearly, a fortuitously resistant clone of organisms is provided with a powerful Darwinian advantage if its competitors are conveniently destroyed by penicillin [257]. This is supported by the recent observation in Atlanta that drug-resistant pneumococcal infection was more commonly found among suburban-dwelling whites who would, as a group, have had readier access to antimicrobial drugs than poorer people living in other less affluent parts of the same city [215,258]. The mechanism of penicillin resistance is *not* due to  $\beta$ -lactamase production but to subtle changes in the penicillin-binding proteins on the cell wall of the pneumococcus, these 'new' proteins having a lower affinity for the penicillin molecule. Once these molecular changes in the penicillin-binding proteins have taken place by genetic remodelling or point mutation, the altered genes may spread horizontally among pneumococcal strains and also geographically as a result of modern modes of world travel. Thus resistant pneumococci are known to spread among small children in daycare centres, this being considered of major epidemiological importance in the dissemination of resistant forms in Iceland where 80% of children attend such centres [259,260].

Decreased susceptibility to penicillin may be defined as 'intermediate' (or low-level resistance) with an MIC of 0.1–1.0 mg/L and 'resistant' (or high-level resistance) with an MIC equal to or greater than 2.0 mg/L. Pneumococci with an MIC of 0.06 mg/L or less are defined as fully susceptible. Thus pneumococcal resistance to penicillin is relative rather than absolute, a recent study in Spain finding that the levels of penicillin resistance that were then current were not associated with increased mortality in

pneumococcal pneumonia, the implication being that this relative resistance can be overcome by usual therapeutic doses [217]. There is thus little evidence linking clinical failure in pneumococcal pneumonia with conventional doses of parenteral penicillin. Unfortunately this is not the case when pneumococci cause infection in less accessible sites such as the meninges, so that the mortality in pneumococcal meningitis is increased by resistant strains [261]. Penicillin-resistant pneumococci also tend to show cross-resistance to other  $\beta$ -lactam antibiotics such as imipenem and third-generation cephalosporins (e.g. cefotaxime and ceftriaxone), which also have reduced activity, pneumococcal resistance to cefotaxime being about 9% in both Spain and the USA [217]. Pneumococcal resistance may also extend to classes of antibiotic beyond the  $\beta$ -lactams. These organisms are sometimes described as multidrug resistant and may display the presence of at least an intermediate level of resistance (as above) to two or more of the following drugs or classes:  $\beta$ -lactams and carbapenems, macrolides, tetracycline, fluoroquinolones, chloramphenicol and trimethoprim, so that vancomycin may be required in the case of meningitis complicating bacteraemic disease caused by resistant pneumococci, all strains having remained susceptible to this drug. *Strep. pneumoniae* resistant to erythromycin are also resistant to the newer macrolides.

### Mortality

The overall mortality from pneumococcal pneumonia in hospital is 5–19% [167,262,263], having been approximately 30% before the advent of antibiotic therapy. The death rate is about twice as high in patients who are found to have bacteraemia and has remained disappointingly static for about four decades, bacteraemia itself occurring in 15–25% of patients [209,263]. Thus the overall mortality from pneumococcal bacteraemia is 18–40% [22,167,209,263–266]. The largest prospective UK study of pneumococcal bacteraemia from the 1980s found the overall mortality to be 28.6% in 325 episodes, falling to 11.8% in those who received antibiotics for at least 24 h [219].

Mortality is related to the antigenic type of *Strep. pneumoniae* responsible for the infection, the type 3 pneumococcus having a sinister reputation. This serotype has been found to have an 18% mortality without bacteraemia, rising to 51% in the presence of bacteraemia (see section on complications) [169]. This accords with a 37% overall mortality rate for the same type in the series of Macfarlane *et al.* [167]. In contrast, the overall mortality for serotypes 1 and 7 was 17 and 10% respectively, whereas no mortality has been reported for non-bacteraemic type 2 infection compared with 10% when this type was associated with bacteraemia [167,169]. These differences are clearly important as the large study of Gransden *et al.* [219] found that type 3

**Table 13.5** Conditions increasing susceptibility to pneumococcal infection and its attendant mortality (see text).

---

Splenectomized state
Functional asplenia or hyposplenia (as in homozygous sickle cell disease, thalassaemia, adult sickle cell disease)
Chronic lung disease
Chronic heart failure
Chronic renal disease (including nephrotic syndrome)
Chronic liver disease (including alcoholism)
Diabetes mellitus
Immunodeficiency states arising as a result of disease or its treatment (including lymphoma, acute leukaemia, chronic lymphocytic leukaemia, multiple myeloma, HIV infection)
Cerebrospinal fluid leaks
Old age (>65 years) and extreme youth (<2 years)

---

was the commonest serotype in adult pneumococcal bacteraemia.

The age of the patient has also been related to mortality, death being more likely to occur in elderly patients [168,263]. Wide age-linked variations have been reported, from 18% mortality for patients in their fifth decade to 83% in patients aged over 90 years [44,209]. Increasing age seems to be an independent risk factor in bacteraemic disease, although this may be accounted for partly by delayed diagnosis and treatment as a result of atypical presentations in the elderly [208,266]. Certainly some physicians have reported the same low mortality rates in those aged over 65 as in those who are younger, provided that antibiotic treatment has been commenced promptly [209]. When death does occur in the elderly, it is usually within 24 h of admission compared with 4–5 days for younger age groups [208]. Other factors that increase the likelihood of mortality include the presence of serious coexisting disease, such as chronic bronchitis and emphysema, congestive heart failure and diabetes mellitus, etc. (Table 13.5). Patients with renal or hepatic insufficiency may suffer a mortality of almost 70% should they develop bacteraemic pneumococcal pneumonia and patients who are immunosuppressed, have associated malignancy or have extrapulmonary infection also have a higher mortality [219,266].

The total number of deaths from pneumococcal pneumonia in a given period of time is a function of the prevalence of influenza during the same period, epidemics of influenza being associated with increased mortality from bacterial pneumonia, of which pneumococcal pneumonia is the most common type [267].

### Complications

Complications of pneumococcal pneumonia include pleural effusion, which may occur in up to 25% of cases. Aspiration should be performed to exclude empyema but the fluid is usually found to be a sterile exudate. Shock and

DIC may occur with serotype 3. Empyema (see Chapter 14) used to occur in 5–8% of patients before antibiotic availability but is now unusual, being found in only 1% overall and in 10% of those with pleural effusions. Lung abscess (see Chapter 15) is rare and when it does occur is usually associated with serotype 3 infection. Purulent pericarditis is also rare and may occur as a result of the direct extension of infection from an empyema [268]. More widely disseminated infection may occur and includes meningitis, peritonitis, endocarditis and septic arthritis. These complications are unusual or rare but may result from the delayed institution of antibiotic therapy. Occasional cases of rhabdomyolysis with myoglobinuric renal failure have been reported, as has massive pulmonary gangrene [269,270].

### *Legionella pneumonia*

*Legionella pneumonia* (Legionnaires' disease) is usually caused by the aquatic organism *Legionella pneumophila*. This first came to light after a serious outbreak of pneumonia affecting over 100 of the delegates attending the 1976 American Legion convention at a hotel in Philadelphia. The circumstances of this outbreak and the deaths that arose from it led to the description of a previously unidentified small aerobic Gram-negative flagellated coccobacillus that was obtained postmortem from the consolidated lungs of four victims [271]. Material from this lung tissue had been inoculated intraperitoneally into guinea-pigs and thence to chick embryo yolk sacs, a procedure usually followed in order to isolate rickettsiae, which were under consideration as a possible cause of the outbreak. The illness became popularly known as Legionnaires' disease and the organism was similarly termed '*Legionella*' [272]. Previously unclassified organisms were subsequently recognized as belonging to the same Legionellaceae family and to have been responsible for undiagnosed febrile illnesses dating back to 1947 [273]. *L. pneumophila* is the most important species in the genus *Legionella* in terms of human pathogenicity, but more than 40 different species have been identified, of which less than half have been shown to be pathogenic in humans. *L. pneumophila* itself has at least 11 serotypes of which group 1 is the predominant cause of human illness, being thought to be responsible for over 80% of all cases of human *Legionella* infection [274,275]. *L. pneumophila* and at least one other species may also cause a benign non-pneumonic influenza-like illness known as Pontiac fever, after the town in Michigan where this epidemic illness was first described [276].

*L. pneumophila* is a small organism and takes up Gram stain poorly, so that it is easily overlooked on microscopy. It is fastidious in its culture medium requirements but can nevertheless be readily grown if these requirements are met. It is possible to identify the *Legionella* sp.

microscopically by fluorescein-tagged monoclonal antibody against a common bacterial membrane protein [277]. *Legionella* spp. live in water, in which medium they are ubiquitous. They are able to multiply extracellularly but may also invade and multiply in aquatic organisms such as amoebae or protozoa [278]. They are able to colonize the water and air-conditioning systems of public buildings such as hotels and hospitals. These sources may be responsible for the sporadic epidemics that continue to attract the popular media, although the majority of cases of pneumonia are sporadic and community-acquired from unknown sources. *L. pneumophila* has been shown to be transmissible to animals by droplet aerosols [279]. *L. pneumophila* is the most pathogenic of the species and accounts for about 90% of reported cases of Legionnaires' disease, a few being attributed to *L. micdadei* (the Pittsburgh pneumonia agent) and *L. bozemanii*.

### Incidence

*Legionella* pneumonia occurs both sporadically in the community at large and less commonly but more dramatically in epidemics clustered about some particular physical location in which the water supply has become contaminated by the organism. A community study carried out retrospectively in the USA found serological evidence of previous *Legionella* pneumonia in 1–2% of the population, giving an estimated incidence of 12 cases per 100 000 per year [280]. These figures may be an underestimate, as only serotype 1 was tested for and as hospital-acquired cases were excluded. A multicentre study carried out under the auspices of the British Thoracic Society found that *L. pneumophila* was responsible for 2% of 453 adult cases of community-acquired pneumonia [281]. Other prospective studies have found higher rates of infection in certain locations. Thus a Nottingham survey of community-acquired pneumonia found *L. pneumophila* to be responsible for 15% of 127 cases during the study period, this organism being the second most common pathogen isolated, whereas a New Zealand study found *Legionella* sp. to be the cause in 11% of 255 cases [126,167]. Legionellosis has been reportedly responsible for even higher proportions of pneumonic infections at some centres in North America [282,283], particularly among severe cases of community-acquired pneumonia needing intensive care [121]. Although it is likely that regional differences in prevalence exist, the enthusiasm with which evidence of *Legionella* infection is pursued is bound to influence the reported infection rate in any centre; thus in the Nottingham study half the patients were not severely ill and the diagnosis of *L. pneumophila* pneumonia would have been missed if a convalescent serum sample had not been tested routinely [284], a retrospective procedure frequently omitted in general hospital practice.

Fluctuations in the number of cases have also been

observed to occur from year to year and seasonally [285]. A follow-up study in Nottingham, carried out 3 years after the original report, found that the proportion of cases had fallen from 15 to 5% [286]. The most consistently reported figure is about 6% [276].

The epidemic form of *Legionella* pneumonia is dependent upon a combination of circumstances that result in the exposure of a sufficiently large number of people to a contaminated source of water. Epidemics occur in buildings such as hotels or hospitals; Wadsworth Veterans Administration Hospital, Los Angeles, experienced over 175 cases during a period of 3 years, at one time over 20 cases occurring within a month. The number of cases declined sharply when the hospital's water supply was chlorinated [287]. It is possible that the wider availability of urinary antigen testing may also result in an apparent increase in the frequency of hospital-acquired cases.

### Epidemiology

*Legionella* pneumonia is most likely to be caused by the inhalation of droplets of contaminated water. There is some evidence to suggest that seasonal factors play a role in sporadic cases of *Legionella* pneumonia, infection having been noted to be more common in the summer and autumn months [167,283,288]. Cases commonly occur in relation to travel on holiday or away from home but this alone is not thought to explain the seasonal pattern. The incubation period is 2–10 days [289]. There is no evidence that any of the *Legionella* spp. can be transmitted from person to person, so that isolation of a case is not necessary. When clustering of cases or epidemics of *Legionella* infection have been investigated thoroughly and to a successful conclusion, the origin of the organism has invariably been tracked down to a source of contaminated warm water that has acted as a reservoir of infection. Such outbreaks may occur in hotels, hospitals and elsewhere [290]. Sources of infection include domestic hot and cold water systems, wet cooling systems (including cooling towers and evaporative condensers), whirlpool and natural spas, humidifiers, ultrasonic mist machines, respiratory therapy equipment and fountains or sprinkler systems [291–296]. Considering that most hot water systems in large buildings are colonized by *L. pneumophila* [297] and that clinical outbreaks are relatively uncommon, it is likely that situations arise in which relative overgrowth of the organism occurs. It is also likely that a significant degree of immunity to *Legionella* infection exists in the community [298], although no test exists for separating those who are immune from those who are not and it appears that cellular rather than humoral immunity is the main defence against infection. Certainly previously healthy individuals may be infected by virulent organisms. However, the attack rate is higher in the elderly, tobacco smokers and those with chronic lung disease, alcoholism and

diabetes mellitus. Patients who are immunocompromised, such as those taking corticosteroids and other immunosuppressive or cytotoxic drugs, are at greater risk of infection and this group particularly includes the recipients of organ transplants [299–302]. *Legionella* pneumonia may occur in patients with HIV infection but there does not seem to be an excess of cases in this group and co-trimoxazole prophylaxis taken for *Pneumocystis carinii* may help to suppress *L. pneumophila* as well [303]. When the disease does occur in this group, however, it tends to be more severe. It is unresolved whether *Legionella* spp. are distributed in mud, soil and horticultural potting media in sufficient quantities to cause sporadic infection [304,305].

Successful epidemiological studies of large outbreaks of *Legionella* pneumonia or Pontiac fever have incriminated either the piped hot water system or vapour from the water coolant of the air conditioning [297]. In the case of hot water systems, *L. pneumophila* has been retrieved more frequently from shower fittings in hospital rooms where infection occurred compared with shower fittings where it had not [306]. Patients who developed infection in a Spanish hotel outbreak were found to have bathed earlier in the morning than those who did not develop infection, suggesting that multiplication of the organism in relatively stagnant water might be an important factor [307]. The organism may also have a predilection for the bases of hot water cylinders [308]. Sudden pressure shocks to a hot water system may also release increased numbers of organisms into free-flowing parts of the supply [287]. Intervention in such cases by either raising the hot water temperature or by introducing chlorination have been successful in controlling outbreaks [307]. It has also been documented that the organism may be transmitted by microaspiration of contaminated water, which may occur with the use of nasogastric tubes and in other situations [285].

The heat exchanger in air conditioning systems of large buildings is cooled by water. The water vapour resulting from this process is usually expelled by fans through a cooling tower, gaining egress through an opening on the roof of the building. Overcontamination of this coolant water with *Legionella* spp. may occur during periods of stagnation, and outbreaks of *Legionella* pneumonia or Pontiac fever have occurred when *Legionella* organisms have been drawn from the plume of water vapour into air conditioning ducts or other ventilation channels [276,309,310].

Occasional cases of legionellosis have been described in connection with bathing in so-called 'spa-whirlpools' and following exposure to lightly oiled water friction coolants in industry [311,312]. No cases have been connected with the large concrete 'natural draught' cooling towers seen in industrial areas and used widely by electricity-generating companies [313].

Species of *Legionella* other than *L. pneumophila* have been

identified as causes of pneumonia in clustered outbreaks acquired in hospitals in which the water supplies have been found to be contaminated. They include *L. micdadei* (the Pittsburgh pneumonia agent) and *L. bozemanii* [314,315].

### Pathology

*Legionella* pneumonia produces gross appearances that resemble those of other severe lower respiratory tract infections. It may develop as areas of bronchopneumonia that cause adjacent lobules to coalesce resulting in lobar consolidation. Consolidation need not be confined to a lobe and is often bilateral in fatal cases. There may be evidence of a fibrinous pleurisy but empyema is rare. Small multiple abscesses may be found in up to 25% of cases coming to postmortem examination [316], and are more common in cases occurring in association with HIV infection. Microscopy shows that areas of consolidation contain an inflammatory cellular exudate within which there are areas of focal haemorrhage and loss of alveolar epithelium [317]. These features do not serve to differentiate pneumonia caused by *Legionella* from that caused by other microorganisms. However, *L. pneumophila* may be demonstrated in areas of inflammation particularly by silver staining, and fluorescent antibody techniques enable the organism to be identified specifically in lung tissue [318] (Fig. 13.10). Electron microscopic studies suggest that the organism divides intracellularly [319]. Resolution of pneumonia may be incomplete in patients who recover, as evidenced by the presence of persistent 'fibrotic' radiographic shadowing [210].

### Clinical features

*Legionella* pneumonia may occur in any age group but is rare in children and the median age of infection is 55 years [288]. It occurs more frequently in men than women, the ratio approaching 3:1. As with pneumococcal pneumonia, it may occur in the previously healthy but also appears to be predisposed to by coexisting illness such as chronic bronchitis, emphysema, diabetes mellitus and immunosuppression. Most paediatric cases of Legionnaires' disease occur in immunosuppressed patients.

It is likely that infection with *L. pneumophila* and other *Legionella* spp. can produce a wide spectrum of illness, much of which doubtless goes undiagnosed. Such infection may range from very mild or subclinical infection with seroconversion to so-called Pontiac fever to pneumonia. Pontiac fever is a supposedly uncommon, self-limiting febrile 'flu-like' illness associated with mild upper respiratory tract symptoms that last for 2–5 days [276]. *Legionella* pneumonia also produces a febrile illness associated with the usual constitutional symptoms, such as malaise, anorexia, myalgia and headache. This is

**Fig. 13.10** (a) Lung biopsy from patient with *Legionella* pneumonia complicating Wegener's granulomatosis showing intra-alveolar inflammatory cells, a mixed inflammatory interstitial infiltrate and hyperplasia of type II cells (haematoxylin & eosin  $\times 110$ ). followed by a cough that may be initially dry but which is often later productive of faintly mucopurulent sputum, which may be flecked with blood. Dyspnoea may occur depending upon the extent of the pneumonia and the presence or absence of pleuritic pain. A relative bradycardia has been reported, especially in the elderly patient. Mental confusion and delirium may be impressive and the pyrexia may exceed  $40^{\circ}\text{C}$ . Diarrhoea has also often been recorded as a feature of the illness, occurring in over 20% of cases. Despite this, prospective studies have shown no particular clinical features that serve to reliably distinguish *Legionella* pneumonia from other pneumonic infection [282]. Extrapulmonary legionellosis is well documented but rare (see section on complications, p. 391).

Similar pneumonic illness may be caused by other *Legionella* spp., although *L. pneumophila* serotype 1 is by far the most common (80%). *L. micdadei*, originally known as the Pittsburgh pneumonia agent, is the most common of

the other pathogenic species, accounting for 8% of infections [320], usually occurring in hospital patients who are immunocompromised [321].

### Investigations

Haematological and biochemical measurements in *Legionella* pneumonia are of low specificity. The white cell count is usually raised but exceeds  $20 \times 10^9/\text{L}$  in fewer than 15% of cases [322,323]. The erythrocyte sedimentation rate and plasma viscosity are usually raised. DIC is reported in common with many other severe infections, but is unusual. Mild abnormalities of liver and renal function including proteinuria and microscopic haematuria are not uncommon [324,325] but have been reported with equal frequency in pneumonia caused by other organisms [282]. Similarly, raised lactate dehydrogenase and creatine kinase levels have also been recorded. However, hypona-

traemia (serum sodium  $<130$  mmol/L), possibly caused by inappropriate secretion of ADH, is more common in *Legionella* pneumonia than in other types, occurring in up to 50% of cases [282].

### Chest radiography

The diagnosis of *Legionella* pneumonia cannot be made on the basis of the chest radiographic appearances as these are very variable and entirely non-specific [210,282]; 90% of patients have a chest radiographic abnormality when first seen [326,327]. Infiltrates may be diffusely distributed, patchy and non-homogeneous, although with increasing consolidation the shadowing may become confluent (Fig. 13.11). Involvement of both lungs may occur in about one-quarter of patients and small pleural effusions have been reported with variable frequency [210,326]. Two further characteristic features are described: the first is that the shadowing may become more extensive despite adequate antibiotic therapy [210], and the second that resolution may be delayed or incomplete, with only one-third of patients having clear lung fields at 1 month and a further proportion having persistent areas of fibrotic scarring [327–329]. Bilateral nodular opacities that may expand and cavitate have been described in immunosuppressed patients, such as those taking systemic corticosteroids [285].

### Microbiological identification

*Legionella* spp. may be very easily missed unless the organisms are specifically sought in patients with pneumonia. This is unlikely to happen unless a knowledgeable person

in the laboratory is persuaded that there is a genuine clinical need, as in the case of a patient with microbiologically undiagnosed severe pneumonia. An adequate sample of sputum that shows few Gram-stained organisms despite the presence of neutrophils should raise the possibility of *Legionella* pneumonia. Morphologically the organisms are small coccobacilli. They take up stain poorly but if staining time is prolonged and basic fuchsin used as a counterstain, they can be demonstrated as Gram-negative coccobacillary rods. However, this is not a productive way of searching for this shy organism.

The usual methods include (i) the determination of antibody level in serum, (ii) the direct demonstration of the organism in body fluids or tissues under the microscope by using immunofluorescent techniques, (iii) the isolation of the organism on special culture media, (iv) the demonstration of antigen in the urine and (v) the detection of the organism using DNA probes and PCR.

The diagnosis in published series is commonly based on retrospective serological information. Most laboratories that have the capability use the microscopic immunofluorescent antibody test (IFAT) on blood to determine the antibody titre, testing for the most common *L. pneumophila* serogroup 1 and often first using the rapid microagglutination test (RMAT) as a screen. An initial blood sample should be taken as soon as possible after the onset of the illness, while the second 'convalescent' sample may be obtained 2–3 weeks later, a fourfold rise in antibody titre to 1/128 or more being diagnostic. Antibody production is commonly delayed, seroconversion at the second week having been found in about 55% of cases [330], so that a third sample at 6–9 weeks may be necessary in epidemiological work. However, a single titre of 1/256 (heat-fixed

**Fig. 13.11** Chest film of a young man who presented with hallucinations, hyponatraemia, fever, cough and diarrhoea showing dense consolidation of the right lung. Sputum smear showed *Legionella pneumophila*.

antigen) or greater for IFAT during convalescence is very suggestive of recent infection in a patient with a compatible illness. A single titre of 1/128 is less sure, as 5–30% of the normal populations have shown this level [331]. Similarly, a single titre of greater than 1/32 for RMAT is very suggestive of infection. Both RMAT and IFAT have a sensitivity of about 80% [332]. A few culture-positive proven cases fail to convert serologically [275].

The specific identification of *Legionella* bacilli in sputum, tracheal aspirates, BAL or lung biopsy tissue (Fig. 13.10) may be carried out rapidly using a monoclonal direct immuno-fluorescent antibody test (DFAT) and can give an answer in 3–4 h. The test is highly specific, false positives rarely occurring, although sensitivity is lower (25–75% for respiratory secretions, 80–90% for lung tissue) since large numbers of organisms need to be present before they can be seen, so that a negative result does not rule out the diagnosis [331]. A monoclonal antibody against a bacterial membrane protein common to all *L. pneumophila* subgroups has been developed for this purpose [277]. Interpretation of DFAT slides under the microscope requires a good deal of skill. This test is less likely to be positive if the radiographic changes are less extensive or if appropriate antimicrobial therapy has been started more than 2–4 days previously.

*Legionella* spp. are fastidious organisms and do not grow on the ordinary media used to process respiratory specimens. It is now possible to attempt routine culture of *L. pneumophila* and the organism can be grown from sputum, tracheal or bronchial aspirates and from lung tissue itself [333]. The choice of medium is important and a commercially produced charcoal yeast extract agar, containing antibiotics to suppress the growth of other organisms, may be used [334]. The reported sensitivity of culture on such selective media using samples from respiratory secretions or lung is better than with DFAT and exceeds 80% [331]. However, relatively few practical workaday laboratories have both the inclination and expertise to carry these cultures out satisfactorily. Isolation from blood cultures is unusual and has been achieved only rarely when blood taken at the onset of the illness is subcultured on to an appropriate solid medium [335].

*Legionella* antigen may also be detected in urine by various methods including radioimmunoassay. The test is specific for *L. pneumophila* serogroup 1, which is somewhat limiting for those in pursuit of excellence. The specificity is very high so that false positives are rare [331]. The sensitivity approaches 80% in serologically confirmed disease with a specificity of greater than 98% and it is a rapid, relatively inexpensive and valuable tool [336] that every properly developed clinical microbiology laboratory should have; those that do not have to rely on empiricism and fast motor cyclists. It has been reported that urine positivity may persist for weeks or months after acute *Legionella* infection [275].

Gene probes based on PCR and using radiolabelled DNA are commercially available to facilitate the rapid identification of *Legionella pneumophila* in clinical specimens such as urine, serum and BAL fluid. The sensitivity is less than with culture of respiratory secretions or lung tissue but of a similar order to that found with DFAT. Less technical skill is required than for DFAT and the gene probe test may remain positive for a few days longer after commencement of treatment. Such testing may also detect species other than *L. pneumophila* [285].

### Treatment

The management of *Legionella* pneumonia should include the usual supportive measures, such as correction of hypoxia, the relief of pain, the maintenance of blood pressure and the correction of fluid and electrolyte balance. Empirical treatment of severe community-acquired pneumonia must cover the possibility of legionellosis.

Antimicrobial therapy for *Legionella* cannot be based on laboratory sensitivities alone because these tend to mislead—effectiveness *in vitro* need not translate into efficacy in patients so that some drugs that appear effective when tested *in vitro*, such as co-amoxiclav and imipenem, are ineffective *in vivo*. This presumably reflects the propensity of the organisms, once engulfed by polymorphs or alveolar macrophages, to multiply intracellularly before disrupting these cells and being released in even greater numbers. The ability to penetrate cells is therefore an essential prerequisite for antibiotics if these are to be successful in destroying or at least limiting the growth of *Legionella* organisms (as is also the case with both *Mycoplasma* and *Chlamydia* infection).

Because of the difficulties and delays in the diagnosis, most of the information on the relative success or failure of antibiotics in treating this disease has been obtained from the interpretation of case fatality reports and there are no controlled trials. Most clinical experience points to erythromycin as the drug of choice [337] but increasing experience with the newer macrolides suggest that they may be as effective [338–340]. Whereas clarithromycin is available for parenteral use, this is not yet universally the case with azithromycin, which has greater intracellular penetration and a long half-life so that 5–10 days of therapy should be sufficient [285]. Tetracyclines and ciprofloxacin have been found to be equally effective and experience with their use is increasing [341,342]. Rifampicin has been shown to be highly active against *Legionella in vivo* and in animal models [343], and experience has accumulated with regard to its use in human *Legionella* pneumonia so that it is used as an ‘add on’ to a macrolide, quinolone or tetracycline in patients with severe microbiologically confirmed Legionnaires’ disease.

An effective dose of erythromycin is 500 mg i.v. 6-hourly (in all but mild infections) for 2 days, continuing with

500 mg orally every 6 h if clinical response is satisfactory. It is recommended that treatment is continued for 2–3 weeks for fear that shorter periods may result in delayed resolution or relapse, particularly in those who are immunosuppressed or who have extensive disease. If infection is judged to be severe or if clinical response is not occurring to erythromycin alone, rifampicin 600 mg 12-hourly either intravenously or orally should be added. The author's own experience and that recorded in the literature suggests that this combination is effective [344]. The use of rifampicin alone is *not* recommended for fear of inducing resistant strains. Parenteral erythromycin tends to cause local phlebitis so that cannulae have to be resited and at high dosage it may cause transient neural deafness. It also commonly produces nausea. If for some reason erythromycin cannot be used, a tetracycline such as doxycycline may be used instead at a dose of 200 mg i.v. for the first dose, followed by 100 mg i.v. 12-hourly for 2 days or until response, and thereafter orally. Alternatively a quinolone such as ciprofloxacin 400 mg i.v. 8-hourly followed 750 mg orally every 12 h may also be used. Ciprofloxacin does not interfere significantly with cyclosporin metabolism, whereas interactions do occur with macrolides and rifampicin, necessitating closer monitoring of cyclosporin levels in organ transplant recipients [338] and thus a quinolone may therefore be preferable in this situation [285].

Other Legionellaceae including *L. micdadei* (Pittsburgh pneumonia agent) can be similarly treated with erythromycin [345] with the addition of rifampicin in severe cases.

### Mortality
